[22]

[23]

[24]

[25]

Other classes of chiral solvating agents function through the formation of host-guest complexes. Most notable among these are chiral crown ethers and cyclodextrins, although host-guest chemistry is an active area of research and reports describing the synthesis of specialized hosts designed to effect specific molecular recognition are increasingly common. Compounds [22]–[25] are examples of chiral crown ethers that induce enantiodiscrimination in the NMR spectra of chiral substrates. Substituents on the crown are responsible for the chirality. The 18-crown-6 unit in [22] and [23] is especially well suited for inclusion complexation of protonated primary amine functionalities.

The chirality in [22] is imparted by the axial chirality of the binaphthyl group; however, steric hindrance from the substituent phenyl groups promotes a greater degree of enantiomeric selectivity. The 5-membered rings are responsible for the chirality of [23]; however, enantio-meric discrimination is promoted through steric effects of the *t*-butyl group. Crown ethers can be used as chiral solvating agents in a variety of solvents, including chloroform, acetonitrile, and methanol. Unlike many other chiral solvating agents, enantiodiscrimination with crown ethers is often enhanced in more polar solvents. The phenolic crown ethers [24] and [25], which each have two sites of chirality from *cis*-cyclohexane-1,2-diol or 1-phenylethane-1,2-diol units, are effective chiral hosts for neutral amines or aminoethanols.

Cyclodextrins are cyclic oligomers, the most common of which contain six (α), seven (β), and eight (γ) D-glucose units (**Figure 6**). The molecules have a tapered cavity with the secondary hydroxyl groups positioned at the larger opening and the primary hydroxyl groups at the smaller. Chiral discrimination most often occurs through differences in hydrogen bonding of the substrate at the secondary opening. Underivatized cyclodextrins are water soluble. Organic-soluble cyclodextrins can be obtained by alkylation of the hydroxyl groups.

The underivatized cyclodextrins are rather unusual in their ability to function as water soluble chiral solvating agents. Enantiomeric resolution is observed in the NMR spectra of a wide range of water-soluble cationic and anionic substrates. Organic-soluble cyclodextrins are one of only a few reagents that can be used to enantiomerically resolve the spectra of hydrocarbons such as tri-substituted allenes, α -pinene, and aromatic hydrocarbons. Amines, alcohols, and carboxylic acids can also be resolved with organic-soluble cyclodextrins.

A set of host compounds of considerable current interest are calix(*n*)arenes [26] and the related resorcarenes [27]. Both sets of compounds form cone-shaped molecules. Calixarenes contain *para* substituted phenol units connected by methylene bridges. The most common have four, six, or eight phenolic units, and by varying the nature of the substituent group or derivatizing the hydroxyl groups an endless variety of calixarenes can be prepared. Chirality can be achieved by one of two means. Inherently chiral calixarenes can be obtained by replacing one of the ring hydrogens on one of the phenol units with a substituent group or by synthesizing a compound in which each of the phenol rings has a different R group. Alternatively, one can attach optically pure R groups or derivatize the hydroxyl groups with an optically pure reagent. The calix

resorcarene [27], in which chirality is achieved by attaching optically pure proline units to the aromatic ring, is suitable for enantiomeric resolution of certain water-soluble aromatic alcohols, amino acid esters, and carboxylic acids in water. Given the current interest in this family of compounds, further developments in this area can be expected.

Chiral liquid crystals consisting of poly- γ -benzyl-L-glutamate have been used in various organic solvents to enantiomerically resolve the NMR spectra of alcohols, amines, carboxylic acids, esters, ethers, epoxides, tosylates, halides, and hydrocarbons. Enantiomeric pairs exhibit different ordering properties in the liquid crystal, leading to different chemical shifts in the ^1H NMR spectra. A more sensitive way to probe distinctions among enantiomers in these systems is to examine deuterium quadrupolar splittings. The disadvantage is that deuterium labelling of the compound under study is then required, although procedures are available for conveniently incorporating deuterium-containing substituents into amines, amino acids, and alcohols.

Lanthanide Shift Reagents

Chiral lanthanide shift reagents are noteworthy because they are effective at inducing enantiomeric resolution in the NMR spectra of such a wide range of compounds. Organic soluble lanthanide shift reagents for hard Lewis bases (primarily oxygen- and nitrogen-containing compounds) consist of tris- β -diketonate complexes in which the ligands are chiral. The most common metals used in such studies are Eu(III), Pr(III), and Yb(III). The lanthanide complex with 3-(*t*-butylhydroxymethylene)-*D*-camphor was the first one to be studied. A large number of chiral lanthanide shift reagents have since been evaluated, and those that are generally most effective and commercially available include complexes with 3-(trifluoroacetyl)-*D*-camphor (facam or tfc), 3-hepta-fluorobutyl-*D*-camphor (hfbc or hfc), and *D*,*D*-dicampholylmethane (dcm) [28]. The shifts in the spectra of substrates are usually larger with chelates of hfbc than with facam; however, the degree of enantiomeric resolution exhibits no consistent pattern. Chelates with dcm are particularly effective at causing enantiomeric resolution. This may be owing, in part, to the steric bulk of the ligand which results in enhanced enantiodistinction of binding substrates.

[28]

Lanthanide tris- β -diketonates rely on association of a lone pair of electrons with the tripositive lanthanide ion, and substantially larger enantiomeric resolution is

observed in non-coordinating solvents. In addition, the reagents are hygroscopic and so the presence of water will significantly reduce the binding of substrates. Examples of the classes of compounds for which lanthanide tris- β -diketonates have been utilized for enantiomeric resolution include alcohols, ketones, esters, lactones, aldehydes, carboxylic acids, ethers, amines, nitrogen heterocycles, amides, lactams, sulfoxides, sulfines, sulfones, sulfoximes, sulfilmines, sulfenamides, thiocarbonyls, phosphorus oxides, and chiral metal complexes that contain ligands with functional groups suitable for direct association with the lanthanide ions.

Chiral lanthanide shift reagents for soft Lewis bases have been prepared by mixing a chiral lanthanide tris- β -diketonate such as $\text{Ln}(\text{facam})_3$ or $\text{Ln}(\text{hfbc})_3$ with a silver β -diketonate such as $\text{Ag}(\text{fod})$ ($\text{fod} = 2,2$ -dimethyl-6,6,7,7,8,8,8-heptafluorooctane-3,5-dione). Addition of the two reagents leads to the formation of a binuclear reagent as illustrated in eqn [3]. The binuclear reagent consists of an ion pair between a lanthanide tetrakis chelate anion and a silver cation.

The silver ion coordinates with the soft Lewis base and the lanthanide induces the shifts. Chiral binuclear reagents have been applied to chiral olefins and aromatics. Binuclear reagents formed using the dcm ligand are not effective for chiral resolution, presumably because this ligand is too sterically hindered to permit formation of the tetrakis chelate anion. Experimentation is often needed to find the correct combination of lanthanide and silver β -diketonate to cause enantiomeric resolution.

Tetrakis chelate anions formed when either a silver or potassium β -diketonate is mixed with a lanthanide tris β -diketonate are effective shift reagents for organic-soluble salts. Adding an organo-halide or fluoroborate salt leads to precipitation of silver halide or potassium fluoroborate, resulting in an organic-soluble ion pair. These reagents have been used to enantiomerically resolve the spectra of chiral isothiuronium and sulfonium ions.

Water-soluble, chiral lanthanide shift reagents with ligands such as (*S*)-[(carboxymethyl)oxy]succinic acid, (*R*)-propylene-1,2-diaminetetraacetic acid, (*S,S*)-ethylene-diamine-*N,N'*-disuccinic acid, *N,N,N',N'*-tetrakis-(2-pyridylmethyl)-(*R*)-propylenediamine, and (*S,S*)-((1*S*,2*S*)-diaminophenylethylene)-*N,N'*-disuccinic acid have been developed. These are especially effective for resolving underivatized α -amino or carboxylic acids. In some cases, consistent trends in relative shift magnitudes are observed which allows the assignment of absolute configurations.

Complex with [29]

Achiral lanthanide shift reagents such as $\text{Eu}(\text{fod})_3$ have been used in a variety of instances, including with MTPA esters, to enhance the resolution in the spectra of diastereoisomers formed from derivitization with an optically pure reagent. The relative shifts in the spectra of the diastereoisomers often show characteristic trends, enabling the assignment of absolute configurations. Achiral lanthanide shift reagents can also be added to solutions of chiral solvating agents and substrates to enhance enantiomeric resolution. Two mechanisms can explain the enhancement.

The first is observed when the chiral solvating agent has a high association with the achiral lanthanide complex. Bonding of the CSA to the lanthanide (Ln) effectively creates a chiral lanthanide shift reagent (Ln-CSA) (eqn [4]). This species then interacts with the chiral substrate (S) to cause enantiomeric resolution (eqns [5] and [6]). The chiral substrate can directly associate with either the lanthanide ion (eqn [5]), or, as observed with certain optically pure chiral carboxylate species, the lanthanide-bonded chiral solvating agent (eqn [6]).

The second mechanism is favoured when the substrate has a much stronger association with the lanthanide complex than the chiral solvating agent. If the enantiomers have different association constants with the chiral

solvating agent, the enantiomer less favourably associated with the solvating agent is more available for complexation with the lanthanide and exhibits larger lanthanide-induced shifts (eqns [7] and [8]).

This mechanism has been observed with perfluoroalkyl carbinols [14] and [15], dinitrobenzoyl derivatives of amino acids [16], 1-(1-naphthyl)-ethylurea derivatives of amino acids [17], and chiral crown ethers [22] and [23]. The lanthanide shift reagent is usually $\text{Ln}(\text{fod})_3$. With crown ether-ammonium salt combinations, lanthanide tetrakis chelate anions of the formula $\text{Ln}(\text{fod})_4^-$ are used.

Lanthanide ions have been covalently attached to either the primary or secondary side of cyclodextrins through a diethylenetriaminepentaacetic acid (DTPA) ligand [29]. Adding Dy(III) to the cyclodextrin-DTPA derivatives can enhance the enantiomeric resolution in the spectra of substrates that form host-guest complexes with the cyclodextrin. Enhancements in enantiomeric resolution are larger with the secondary derivative, which is consistent with the observation that enantiodiscrimination with cyclodextrins usually involves interactions with the hydroxyl groups on the secondary opening of the cavity.

Conclusions

The number of available chiral derivatizing agents, solvating agents, and lanthanide shift reagents provides the possibility of enantiomerically resolving the NMR spectra of a wide variety of compound classes. Furthermore, in many instances the mechanism that leads to the enantiomeric resolution is well enough understood that it is possible to assign absolute configurations based on the relative shift order. Since none of the reagents is ever 100% effective, experimentation with several resolving agents may be necessary. Given the increasing interest in knowing and controlling the optical purity of chemicals, a better understanding of existing systems and the development of additional reagents for enantiomeric discrimination in NMR spectroscopy seems to be assured.

We consider the determination of the concentration of elements in various materials studied in agricultural and environmental applications, by the use of the following methods: atomic absorption spectroscopy (AAS) using a flame (FAAS) or a graphite furnace (GFAAS) as an atom cell; inductively coupled plasma atomic emission spectroscopy (ICPAES); inductively coupled plasma mass spectrometry (ICPMS) and X-ray fluorescence (XRF). The analytical characteristics of the methods as normally practised are compared with the requirements of fitness for purpose in the examination of soils and sediments, waters, dusts and air particulates, and animal and plant tissue. However, there are numerous specialized techniques that cannot be included here.

Introduction

Environmental and agricultural studies involve a number of different materials that need to be analysed. The principal test materials encountered by the analyst in this sector are soils, sediments, air, dusts, water, plant material and animal tissue. For completely practical reasons, we need to know the composition of these media over wide concentration ranges, from major constituents to elements at ultratrace levels. One is especially interested in the way elements are transferred between media, their biological role and metabolic pathways, and their ultimate fate.

Almost invariably in these applications we can be satisfied if the analytical result obtained is within a range of 90–110% of the true result. This modest fitness-for-purpose requirement is an outcome of the high uncertainties in sampling of environmental materials. In these circumstances, the total uncertainty (sampling plus analytical) is not improved by the use of high-accuracy analytical methods. Overall, therefore, it is a more effective use of resources to analyse a larger number of samples with only moderate accuracy.

Atomic spectroscopy is almost exclusively the method of choice in the determination of concentrations of elements in agricultural and environmental studies. There are several reasons for this: (a) for the most part no separations are needed before the measurement, only a

straightforward dissolution procedure; (b) test materials can be analysed in rapid succession; (c) elements can be determined at suitably low concentrations; (d) apart from atomic absorption, atomic spectroscopy methods are suitable for determining many elements simultaneously; (e) modern atomic spectroscopy methods can easily fulfil the accuracy requirement specified above. No other methods can match this range of performance. Where speciation studies require a preliminary separation of the analytes, atomic spectroscopy is often the method used in 'hyphenated' methods to provide a very sensitive and virtually specific detector for almost any element.

In the following sections we consider the key features of the atomic spectroscopy methods, how they relate to user requirements, and how they are applied to specific types of test materials. Although only laboratory-based methods are considered here, it must be recalled that field methods sometimes find worthwhile applications: XRF is one atomic spectroscopy method that is available as a truly portable instrument.

Detection Limits

The detection limit is (informally) the lowest concentration of the analyte that can be reliably detected, and is a reflection of the precision of the instrumental response obtained by the method when the concentration of the analyte is zero. Obviously, if the uncertainty range of the measurement (at some specified level of probability) includes zero, we are not sure that the analyte has been detected. However, detection limits as supplied in the literature and manufacturers' brochures can be misleading to the unwary. Their magnitude depends critically on the conditions under which the precision was estimated. Manufacturers and method developers usually quote 'instrumental detection limits', where the precision is estimated on the pure solvent (or other matrix) in the shortest possible time, with no adjustments at all to the instrument.

Such detection limits usually need to be adjusted before they can be applied to the analysis of real materials, *inter alia* to allow for the 'dilution' of the analytes. For instance, in the analysis of a soil, a 0.1 g test portion may be treated with reagents and the analytes liberated

into solution may be made up to a volume of 10.00 mL for presentation to the instrument. The analytes have been diluted by a factor of 100, in that an element at a concentration of 100 ppm in the soil will be presented to the instrument at a concentration of 1 ppm in the test solution. In addition, in 'real analysis', many features other than short-term instrumental variation play a part in the variability of results. Thus, detection limits estimated under repeatability or reproducibility conditions may be considerably higher than simple dilution-adjusted instrumental detection limits, by as much as an order of magnitude. We here consider instrumental detection limits, adjusted for dilution and with an extra factor of 5 to convert them roughly to repeatability detection limits.

The detection limit also depends critically on details of the instrumentation. For example, magnetic sector ICPMS provides detection limits lower than those of quadrupole instruments by between one and two orders of magnitude.

Among the atomic spectroscopy methods, flame and furnace methods have very variable detection limits, because they are affected by variations among the elements in terms of efficiency of atomization and efficiency of ionization. ICPAES and ICPMS show a smaller range of detection limits, because atomization is uniformly close to 100% efficient, and the efficiency of ionization accounts for much of the remaining differences. Thus, in ICPMS, elements more difficult to ionize (e.g. nonmetals) have higher detection limits. The outcome is that FAAS, being fast, cheap and robust, is used for a limited range of more abundant elements. GFAAS, being slow and requiring much care, but with much lower detection limits for some elements, is used on a much more restricted scale, typically for low trace elements such as lead and cadmium in food and drink. ICPAES is fast and robust and moderately priced, and is widely used as the workhorse method for major and trace elements, with instrumental detection limits typically 1–50 ppb (parts per 10^9). ICPMS is unique in the very low detection limits obtainable in simultaneous analysis, typically 0.1–10 ppt (parts per 10^{12}), but it requires a high dilution factor (typically 500–1000), is more expensive, and is more prone to downtime. In XRF methods, the detection limit is poor for light elements but roughly constant at a few ppm for elements heavier than iron, and the method usually requires only small dilution factors.

Asymptotic Precision

The other aspect of precision that affects the judgement of instrumental analysis can be called 'asymptotic precision', which is precision estimated at a concentration orders of magnitude above the detection limit. Under that condition we usually find that relative precision is

Figure 1 Relationship between precision of measurement (as relative standard deviation) and concentration of analyte (expressed in units of multiples of detection limit). The graph shows the sharp fall in relative standard deviation just above the detection limit, and the comparatively steady values in the preferred working range.

concentration invariant, i.e. the relative standard deviation (RSD) is constant. Thus, in general, with increasing concentration the asymptotic precision always increases, but the relative standard deviation falls sharply, from about 30% at the detection limit, to close to the asymptotic level at 20–100 times the detection limit (**Figure 1**). Usually we try to arrange matters so that we make measurements at these near-asymptotic precisions.

Asymptotic precisions for atomic spectrometry methods depend not only on the type of instrumentation, but also on other factors such as the protocols used for calibration and measurement, and whether internal standardization has been used. Typical between-run values as RSDs are: FAAS, 1.5%; GFAAS, 5%; ICPAES, 1%; ICPMS, 3%; XRF, 0.5–1%.

Abundance–Detection Limit (ADL) Diagrams

A convenient way of summarizing the applicability of the various methods to various types of test materials, over the range of relevant elements, is the use of abundance–detection limit (ADL) diagrams. For each element in these diagrams, the detection limit of the method (d) is plotted against the median concentration found in the sampling medium in question (the abundance, a). (The detection limit is adjusted for a likely dilution factor and with an extra allowance to convert instrumental detection limits into between-run detection limits.) Both variables are expressed as mass fractions (e.g. 1 ppm $\equiv 10^{-6}$) and plotted on $\log_{10}$ scales. (Frequency distributions of concentrations of trace elements in randomly selected agricultural and environmental media are usually strongly skewed to the positive tail, so lower concentrations are well represented by the median. In any

Figure 2 The layout of an ADL (abundance–detection limit) diagram, showing the for interpretation for elements that plot in the various regions of the diagram. The concentration units used for both axes are mass fractions.

event, information on percentiles other than the median is difficult to compile.)

ADL diagrams are divided into four zones (**Figure 2**) by three lines: (i) $d = a/10$; (ii) $d = a$; and (iii) $d = 10a$. Elements plotting to the right of and below line (ii) can be determined with at least moderately good precision at normal concentrations. Line (i) represents concentrations at $10\times$ the detection limit, at which the elements can be determined with a relative precision of about 5%. Elements plotting to the right of and below this line can therefore be determined with completely acceptable precision, and those plotting between lines (i) and (ii) with moderate precision. Elements between lines (ii) and (iii) can be determined with moderate precision only after a $10\times$ preconcentration, while elements above or to the left of line (iii) can be determined only if preconcentrated to a degree greater than tenfold. These diagrams will be used to compare the capabilities of the various methods.

Interference Effects

Another figure of merit that describes the quality of the data produced in atomic spectroscopy is ‘trueness’, which, in the absence of analytical blunders, is synonymous with lack of interference. Interference is defined as the influence on the analytical signal relating to an analyte caused by constituents of the test materials other than the analyte (the concomitants). Broadly, atomic spectroscopy is affected by interference to a remarkably low extent. However, interference is not absent and

usually has to be taken seriously. Fortunately, there are well-established analytical techniques for obviating the effects of interference that are eminently applicable to atomic spectroscopy.

Interference effects are often spectral in origin. In atomic emission and absorption they result when a concomitant gives rise either to photons close to the same wavelength as the analyte (spectral overlap) or to photons of another wavelength that inadvertently arrive at the detector (stray light). Methods for overcoming such spectral problems usually involve either a separate estimation of the background to a spectral line, or estimation of the concomitant concentration at another region of the spectrum and the calculation therefrom of an appropriate correction term. These features are built into modern instruments and their software, but the correction procedure may degrade other aspects of performance such as the detection limit. Comparable problems occur in mass spectrometry.

Nonspectral interferences are called matrix effects. In free-atom methods, matrix effects often reflect changes in the efficiency of atomization of the analyte or of excitation of the separate atoms produced in the atom cell. In FAAS and ICPAES, changes in the physical characteristics of the test solutions (e.g. surface tension, viscosity, density) may additionally affect the efficiency of the nebulizer. However, matrix effects seldom cause errors of greater than $\pm 5\%$ and can often be ignored in agricultural and environmental studies. In GFAAS, by contrast, the composition of the matrix is crucial in determining the atomization efficiency, and needs to be carefully controlled. Likewise, in XRF the gross composition of the pellet or bead may affect the intensity of fluorescent X-rays.

There are a number of convenient and effective ways of handling matrix effects. Where the gross composition of the test materials is effectively constant, it is sufficient to calibrate the instrument with matrix-matched calibrators. Even when test materials are also variable, they may sometimes be matched with calibrators by swamping the native matrix with a much larger quantity of a matrix modifier. This technique is commonly used in FAAS, GFAAS and XRF methods. If matrix matching is not possible, the method of analyte additions is always applicable, if somewhat laborious, to methods with linear calibration functions. In XRF a set of complex correction equations based on the major composition is used to correct for matrix effects.

Performance Enhancement by Chemical Pretreatment

The detecting power of all of these methods can be improved by preconcentration after the initial decomposition of the test material. This procedure, effected

by methods such as ion-exchange, solvent extraction or solid-phase extraction, is very effective. It often has the additional advantage of removing the analytes from their original matrix and thereby considerably reducing matrix effects. Concentration by a factor of 10 is straightforward, and by 100 is usually feasible. For the atomization methods it is convenient, after the initial separation, to return the analytes to a small volume of aqueous medium. Trace elements can also be analysed directly in organic solvents. This is not a popular option, although there are no inordinate difficulties about the procedure. Different options for presenting the separated analytes exist in XRF, for instance trace analytes can be concentrated by passing the test solution through an ion-exchange membrane and analysing the membrane in a specially designed holder.

Another widely used method of improving detection limits is the injection of certain elements in the gas phase. The elements Ge, Sn, Pb, As, Sb, Bi, Se and Te all readily form hydrides in acidic aqueous media on reduction with sodium tetrahydroborate. As the hydrides are not very soluble in water, they can be readily transferred into the gas phase and thus completely separated from the matrix. The efficiency of hydride formation is high (often approaching 100%), so that detection limits for these elements can be improved by a factor of 100 without problems.

Speed of Analysis

Speed of analysis is one of the attractive features of the atomic spectroscopy methods described here. An important discrimination can be made, however, between methods that determine elements sequentially and those, clearly much faster overall, that can determine a whole suite of elements simultaneously. In methods involving nebulization, the critical determinant is the time taken for the system to 'wash out', so that material from one test solution is completely replaced by its successor in the analytical system and a new stable signal established. It usually takes only a few seconds subsequently to make a measurement of the signal intensity. Such sample changeovers can be as short as 15 s, but are usually longer (1–2 min) because of poor attention to design in this aspect of commercial instrumentation. In GFAAS the speed of analysis is largely controlled by the time needed for the furnace to cool sufficiently before introduction of the next sample. XRF exhibits different properties. It may require a substantial time for the signal to be collected (minutes), whereas the exchange of one test material for the next takes only seconds (because only solids in special holders are moved).

The question of speed is related to the reliability of the instrumentation. Reliable methods with low operating costs can readily be automated and can left unattended, e.g. overnight. In those circumstances, speed

may be a secondary consideration. XRF methods come into this category. For methods that are more prone to problems during running (and so cannot be left unattended) or that use expensive consumables (e.g. argon for ICP methods), speed is usually of the essence.

Instrumental Reliability and Stability

Reliability is also a key feature in the comparison of methods. Some methods are inherently reliable and stable, e.g. XRF. The signal obtained from an analyte in a particular material will vary only slightly from run to run, so that calibrations have to be updated only infrequently. The situation is quite different in methods requiring nebulization and/or atomization, because there the stability of the signal depends on such variables as power input, gas flows, etc. In ICP methods particularly, the efficiency of atomization can occasionally vary suddenly due to partial blockages in the nebulizer or in the injector tip of the plasma torch. Vigilance is required for early detection of such problems. In addition, in ICPMS, drift may be caused by gradual occlusion of the orifice in the sampling cone (part of the plasma-MS interface) by material passing through the plasma. This problem must be minimized by the use of high dilutions (i.e. at least 1:500) or by the use of flow injection to deliver the test solutions in short slugs, or its effects may be alleviated by the employment of an internal standard.

Ease of Calibration

Two features contribute to ease of calibration in analytical methods, (a) linearity over a wide concentration range, and (b) use of solutions (rather than solids) to present the analyte to the instrument.

Linearity makes calibration simple by limiting to two the number of calibrators necessary to estimate the calibration function for a single analyte. A nearly (but not necessarily completely) linear calibration over a considerable concentration range (e.g. more than four orders of magnitude) is also essential in multielement calibration, where major and trace constituents are determined simultaneously.

Preparation of calibrators in solution can be effected by simple mixing of the correct amounts of the constituents in an appropriate matrix. There is little problem with either homogeneity or speciation of the analytes in that instance. This consideration applies directly to conventional ways of operating AAS, ICPAES and ICPMS. It also applies to XRF methods that employ fused beads, where the test material is homogenized in a flux. (The end-product is, of course, a solid solution.) Where solid calibrators are used, more problems are usually encountered. The most common of such are problems of creating a sufficiently homogeneous mixture of the analytes in a realistic matrix, and problems of

speciation of the analyte. Fortunately, neither of these is a serious problem in routine XRF, although they may be in specialist applications of ICPAES and ICPMS, such as laser ablation work.

There are special problems associated with multi-element calibration when more than a few elements are required. First, it is necessary to provide a set of calibrators that span the range of the test materials adequately. This is simple if there are no constraints on the design of the calibrator set. Often there are such constraints. For instance, for major constituents, it is not realistic (and sometimes not even possible) to have all of the major constituents at their maximum concentration in a single calibrator. In consequence, methods such as serial dilution of a single concentrated solution cannot be undertaken, and more complex designs are required. Constraints due to minor interferences apply to methods such as ICPAES. In some styles of calibration for major and trace elements simultaneously, there are minor deviations from linearity and small interference effects from major constituents that have to be taken into account. Finally, the calibration set must be designed to avoid major matrix mismatches with the test materials.

In XRF it is common for practitioners to calibrate with reference materials. As these are natural materials, designs cannot be made optimal. It would in fact be easier and more accurate to use pure stoichiometric compounds to synthesize calibrators, just as in liquid solution work, and this strategy would allow optimal designs.

Soils and Sediments

Soil is the key medium in environmental and agricultural studies of the distribution of the elements. Soils and sediments are the main repositories of trace metals. For conventional analysis by AAS and ICP methods, it is necessary to bring the analytes into solution. This is usually effected by treatment of the test material with strong mineral acid mixtures. In many instances a complete dissolution of the soil is not required. Most elements of agricultural or environmental import can be sufficiently solubilized by evaporation with nitric and perchloric acids, followed by a dissolution with hydrochloric acid. Any elements remaining undissolved after this type of treatment will hardly be of significance to living organisms. An attempt at studying the bioavailability of significant metals can be made by the use of 'selective extractants'. These are designed to enable experimenters to distinguish between categories such as 'readily exchangeable', 'organic bound', etc.

By making some reasonable assumptions about dilution factors and the relationship between instrumental and repeatability detection limits, it is possible to construct ADL diagrams for soils analysed by the various atomic

spectroscopy methods. These are shown in **Figures 3–6** for a selection of key elements. A surprisingly uniform picture emerges, with only ICPMS being suitable for the direct determination of elements such as As, Cd, Hg, Mo, Se and U, a range of important essential or toxic elements of low abundance. However, preconcentration or other sensitivity-enhancing methods can usually render these elements capable of determination by AES or AAS

methods. Of the methods considered here, perhaps the least applicable is FAAS, which is also probably the most laborious, being a single-element method.

Water

Fresh water is in many ways an ideal medium for analysis by the atomization methods. It is ready for direct analysis

with virtually no pretreatment, and no dilution is required. Matrix effects are usually negligible or easily handled. The method *par excellence* for water analysis is ICPMS (**Figure 7**), which can be used to determine most of the elements directly. Another important method here is GFAAS which, although undoubtedly slow, can be used very effectively for a range of useful trace elements. The main problem with the remaining methods (**Figure 8**) is that many important elements are present in fresh waters at very low concentrations, below the detection limits for direct determination by most AAS and AES methods. For most elements this drawback can readily be overcome by preconcentration. Simple evaporation is effective for 10–20-fold preconcentration, without causing serious matrix effects. Matrix separations are also simple and useful. For example, elements such as Cd, Cu, Fe, Mn, Pb and Zn can be determined by FAAS or ICPAES after solvent extraction or ion exchange.

Sea water and other saline waters pose some problems for the atomization methods. Nebulizers for the ICP tend to become blocked with salt encrustations with a disastrous effect on sensitivity. This can be overcome in direct analysis by flow injection techniques, or by the use of 'high-solids' nebulizers. Dilution also helps here but, of course, degrades the detection limits. The sampling cone in ICPMS equipment is also prone to be gradually occluded when high-solids solutions are sprayed. Again, preconcentration techniques that provide a separation of the analytes from the matrix are very useful in this context.

The speciation of certain elements in water is important, as it throws light on the transport of the elements

Figure 8 ADL diagram for water analysed by inductively coupled plasma atomic emission spectroscopy. (For explanation see Figure 2.)

between other media, e.g. the soil–plant interface. In this context, atomic spectrometry has the role of providing a sensitive and virtually specific detector for the individual elements, after some preliminary process such as chemical separation or chromatography.

Air and Dust

Metallic elements are present in air mostly as particulate material, which can be removed *inter alia* by filtration. Dusts are simply air particulates that have collected naturally by gravitation. Atomic spectrometry methods are well adapted to the analysis of used air filters. For instance, filters of the cellulose acetate type can conveniently be destroyed by oxidation with nitric/perchloric acid while the metallic elements are thereby solubilized. The resulting aqueous solution, of small volume, can be analysed simultaneously for many elements by ICPAES or ICPMS. The former is quite capable of determining most elements at their threshold concentration after the filtration of (say) 10 litres of air. Alternatively, air filters have a suitable form for direct analysis by XRF in special filter holders.

Biological Tissues

Animal and plant tissues are usually prepared for elemental analysis by destruction of the organic matrix by oxidation, either in a furnace (dry ashing) or by the use of oxidizing acids (wet ashing). The two methods have similar outcomes in most respects, except that there is a

Figure 9 ADL diagram for plant material analysed by inductively coupled plasma mass spectrometry. (For explanation see Figure 2.)

Figure 10 ADL diagram for plant material analysed by inductively coupled plasma atomic emission spectroscopy. (For explanation see Figure 2.)

tendency for volatile elements such as As and Se and even Cd to be lost during dry ashing, especially if the temperature is allowed to rise above 500 °C. The normal outcome is for the elements to be nebulized from a dilute solution of hydrochloric acid. Matrix effects are not usually troublesome in this sector, although some materials high in calcium, potassium or phosphorus may require special attention. **Figures 9 and 10** show

the applicabilities of ICPMS and ICPAES for plant material. Concentrations of elements in animal tissues are broadly similar, although there are contrasts in certain cases.

Introduction

Electronic spectroscopy is widely used to detect environmental contamination. Environmental applications of electronic spectroscopy involve challenging analytical problems. Both qualitative identification and quantitative determination are performed for analytes which may occur at concentrations ranging from parts per hundred to parts per quadrillion. The analytes occur in a very wide range of matrices. Electronic spectroscopy consists of monitoring the absorption of light by the sample or monitoring the emission of light, often after excitation of the sample by an appropriate light source or laser beam. Both inorganic and organic analytes can be detected. Real-world samples are often complex mixtures, and therefore environmental applications may involve coupling a separation technique with electronic spectroscopy. Separation techniques include liquid chromatography (LC), gas chromatography (GC), high-performance liquid chromatography (HPLC), capillary electrophoresis (CE), and immunochemical analysis. Emerging techniques include the increasing use of hybrid techniques and the development of highly parallel detection instruments.

The Analytical Problem

The environmental analytical problem generally presents two questions: what substances are present in an environmental sample and how much of each of the substances is there? Sometimes these questions can be answered by spectroscopic techniques in a direct manner with little sample handling. However, the range of needs encompasses a vast array of matrices and levels of determination. To indicate some scope to the problem consider a list of potential matrices: soil, sediment, water, plants, animals, fly ash, sludge, waste water, leachates, food, blood, urine, hair (fur), drinking water, commercial pesticide formulations, air, dust, automobile and truck exhaust, and rain. The various matrices require extraction techniques, cleanup techniques, and often a final separation or detection technique. Contaminant levels range from percent levels (part per hundred) to parts per quadrillion (pg kg^{-1}). To give some realism to these numbers, for example, pesticides in formulations may be

present at percentage levels. In another context, contaminants at Superfund sites are often found in the parts per million ($\mu\text{g g}^{-1}$) level. (A Superfund site is an identified site under the authorities of the Comprehensive Environmental Response, Compensation and Liability Act where releases of hazardous substances had already occurred or might occur and posed a serious threat to human, health, welfare or the environment.) Near the other extreme, the European Union regulates phenoxy-acid herbicides at the 100 parts per trillion (pg g^{-1}) level in drinking water.

The applications, therefore, fall into two broad categories: qualitative identification and quantitative determination of substances or classes of compounds in environmental matrices. The qualitative identification is usually accomplished by acquiring a full UV-visible absorption or emission spectrum of the compound of interest. This spectrum is then compared with libraries of spectra for potential matches. Usually, the specificity of this match does not produce the same level of certainty as could be obtained from a mass spectrum that has been properly matched to a library spectrum. Nevertheless, within the context of a limited number of compounds and a particular analysis, some degree of certainty is obtained. In some favourable cases (e.g. fluorescence of oils), UV-visible identification has prevailed in legal proceedings and shown similar degrees of certainty to GC-MS. In UV-visible identifications, comparison is often made to site-specific standards, rather than against a library. The certainty of identification by UV-visible can be enhanced by the association of a retention time or migration time achieved by employing one or more separation techniques in combination with the spectroscopic data obtained on-the-fly.

The identification problem or the specificity of the determination can be a complicated matter because of the large number of analytes, matrix components, and the variability of environmental matrices depending upon location. There are now over 11 million organic compounds recognized by the *Chemical Abstracts Registry*, with over 30 000 compounds considered as chemicals of commerce, and perhaps 500 to 1000 routinely measured as members of industrial solvents, disinfection by-products, insecticides, PNAs, herbicides, organochlorine

pesticides, PCBs, phenols, anilines, benzidines, and potential endocrine-disrupting compounds.

The quantitative determination is usually based on the absorption of light at some fixed wavelength or wavelengths, the selection of a wavelength for quantitation from the diode array detection (DAD) data, or, in fluorescence detection, the emission of light at some fixed wavelength (or band) while exciting at a fixed wavelength. For even better quantitation, one monitors the area under a peak or area of the whole spectrum. Thus one may monitor absorption at 214 nm for the sensitive detection of many compounds. Alternatively, one may monitor emission at 520 nm with excitation at 488 nm for the sensitive fluorescence detection of fluorescein and fluorescein-related compounds.

Inorganic Compounds

Electronic fluorescence techniques may be used to detect inorganic compounds, which exist as ions in solution, using one of several methods. Photoluminescence (or simply luminescence) refers to the photoexcitation of an analyte in solution, caused by absorption of visible or ultraviolet radiation, followed by emission at a longer wavelength. Luminescence is classified as either fluorescence or phosphorescence. Fluorescence is an allowed radiative transition from the first excited singlet state, while phosphorescence is a spin-forbidden transition from the first excited triplet state. Typical fluorescence lifetimes are nanoseconds to sub-microseconds, while typical phosphorescence lifetimes are microseconds to seconds. For many inorganic substances, fluorimetric methods are the best analytical methods.

- (1) If the inorganic ion luminesces in solution, it may be detected simply by placing the ion in an appropriate solution. This technique works primarily for rare earths and uranyl (UO_2^{+}) compounds. When combined with an inorganic reagent (e.g. HCl, HBr, etc.), the technique works for some group 3–5 elements.

Since the rare earths and uranyl compounds luminesce in solution, these ions may be detected by 'native fluorescence'. Even though the bare ion fluoresces in these cases, the luminescence intensities can be greatly enhanced by appropriate complexation. The spectrum may be broad or narrow, depending upon the element and the nature of the electronic transition involved: the fluorescence spectrum is broad for Ce(III), Pr(III), and Nd(III), because they result from electron transitions from the 5d to the 4f shell. For example, cerium salts fluoresce in a broad band from 330 to 402 nm. In contrast, the luminescence spectra of Sm(III), Eu(III), Td(III), and Dy(III) are narrow, consisting of a few characteristic bands because they result from

transitions of the 4f electron, and the f electron is little perturbed by its environment. For example, Gd has a single bright, narrow band at 311 nm. Sensitive fluorimetric methods have been developed for Pr, Nd, Sm, Eu, Gd, Tb, Dy, Er, and Tm. Detection limits range from 50 picograms to a microgram depending on the rare earth. Uranyl (UO_2^{+}) ions phosphoresce in several bands in the 460–620 nm range. The uranyl ion is typically detected in acid solution. The fluorescence efficiency depends on pH and on impurities. Many organic compounds can quench the luminescence from uranyl. In phosphoric acid or phosphate solutions uranyl can be detected at 5 parts per trillion.

- (2) If the inorganic ion does not luminesce in solution, the ion may be combined with an organic ligand to yield a metal chelate. In favourable cases, the isolated ligand does not fluoresce, but the metal chelate does fluoresce, allowing for sensitive detection of the ion. In other cases where the complexing agent luminesces, the metal complex is still shifted enough in peak position to be detected even in the presence of the free agent. Over 40 different metals have been determined by this technique. When this method is applicable it is very sensitive and specific. For example, gold may be detected by its formation of a complex with Rhodamine B in 0.4 M HCl. Using excitation and detection wavelengths of 550 and 575 nm, respectively, as little as 20 ppb of Au can be detected, a level 25 times more sensitive than atomic absorption. In another example, cyanide (CN^{-}) can be detected at levels of 0.2 μg by complexing with *p*-benzoquinone to yield an intense green fluorescence. Sulfide, thiosulfate, thiocyanate, ferrocyanide, and 26 other ions had no effect.

Several kinds of reaction between inorganic analyte and the organic reagent are possible: binary or ternary complex formation, substitution, redox, catalytic, and enzymatic. This technique can sometimes be applied to both cations and anions. Examples of commonly used reagents are 8-hydroxyquinoline, azo reagents, Schiff's bases, hydrozones, hydroxyflavones and chromone derivatives, and anthraquinones.

- (3) If neither of the above approaches works, 'indirect detection' may be employed. The inorganic ion may quench the fluorescence of a second compound, in which case the analyte is detected as a decrease in the fluorescence of the second compound. For example, most assays for fluoride (F^{-}) are based on the decrease in fluorescence of an Al or Zr chelate due to subsequent fluoride complex formation (AlF_6^{-} or ZrF_6^{-}). Quenching is generally less sensitive and less selective than fluorescence. Alternatively, the analyte may cause the release of a ligand which then reacts to form a fluorescent product.

Most fluorimetric determinations of inorganic species are equilibrium methods in which the reaction goes to completion. However, in some cases kinetic methods are used, in which the initial reaction rate is linearly related to the initial analyte concentration. For example, platinum(IV) can be detected at 0.2–0.6 ppm levels using a reaction with di-2-pyridylketone hydrozone, yielding a blue auto-oxidation product, whose rate of appearance is measured at 435 nm with an excitation wavelength of 359 nm.

Organic Compounds

Organic compounds are often of major concern in environmental applications. In this section we discuss the detection of organic compounds by electronic absorption and luminescence spectroscopy.

The technique of UV-visible absorption spectroscopy is a mature technology which is widely used for detection. A beam of light whose wavelength is in the visible or ultraviolet range traverses a sample containing the sample. The signal is detected as a decrease in the intensity of the light. UV-visible absorption spectroscopy has a moderate sensitivity and a low to moderate specificity. The specificity is low because many compounds absorb in the same general wavelength range. Because of the low specificity, this technique can be used for real-world samples of low to moderate complexity. The technique works best for unsaturated compounds (aromatic, polycyclic aromatic or heterocyclic). In these cases, often there is enough vibrational structure for relatively good specificity. It works for dyes and for colorimetric reaction products.

The second technique is UV-visible luminescence, meaning either fluorescence or phosphorescence. When this technique is applicable it can be very sensitive, especially with laser excitation. In aqueous solution, the sensitivity can be parts per billion to parts per trillion. Luminescence is more sensitive than absorption because in the former case one is detecting an increase from a very small background, while in the latter case one is detecting a decrease from a large background. The technique is applicable to aromatics, most polycyclic aromatics and their derivatives, and some heterocycles. For many polycyclic aromatic hydrocarbons, the vibrational structure is sufficient to greatly enhance specificity. It can be applied to many other analytes, using fluorimetric reagents. The selectivity can be enhanced by varying the wavelength of excitation and the wavelength of detection, or by using time or phase resolution.

One of the problems that arise in luminescence studies of large molecules is that the spectrum may be relatively broad and unstructured. Accordingly, in a real-world sample there can be interferences caused by other compounds. One technique to improve the specificity is

‘synchronous luminescence’, in which both the excitation wavelength and detection are scanned, usually with a fixed difference between the two wavelengths. This tends to sharpen the spectra, reducing the problem of interferences and thereby improving the specificity of the technique. On theoretical grounds, it makes more sense to scan the two wavelengths with a fixed difference in the photon energy, rather than a fixed difference in the wavelength.

Luminescence is applicable to polyaromatic compounds, fluorescent dyes, fluorimetric reaction products, polychlorinated biphenyls (PCBs), phenols, 50% of pesticides, many semivolatiles, many nonvolatiles, and petroleum oils. For luminescence to work, the compound must fluoresce. However, many large molecules absorb but do not fluoresce in the visible or UV. For such non-fluorescing compounds, absorption spectroscopy must be used instead (with much less sensitivity) or, alternatively, the organics can sometimes be complexed.

In practical applications, these spectroscopic techniques are often used for field screening, in which samples are screened in the field rather than being transported to the laboratory for traditional analysis, which can mean a delay of up to a month in obtaining the results of analysis. Recent technical advances include: more compact lasers, miniaturized optical hardware, new types of detectors, increased use of fibre optics, and better computer software for spectral data processing and pattern recognition.

The Problem of Spectral Congestion

Many real-world samples consist of a large number of substances whose spectra are relatively broad and relatively featureless. This limits the ability to discriminate between compounds with similar or substantially overlapping spectra. There are two techniques that can be used to discriminate between compounds that are spectrally overlapping. One technique is discrimination based on fluorescent lifetime. Two compounds that spectrally overlap can be distinguished by their fluorescence lifetimes, provided that their fluorescent lifetimes are sufficiently different. The second technique is chromatographic discrimination; i.e. the use of a separation technique.

Separations Coupled with Electronic Spectroscopy

In some cases, e.g. forensic oil identification, the spectra of mixtures of fluorescent compounds may themselves be of interest for fingerprinting purposes, especially when combined with chemometric or pattern recognition techniques. Many real-world environmental problems

involve large numbers of compounds, and the spectra of individual compounds are needed for identification and quantitation. Detection techniques are often preceded by a separation step. Historically, the workhorse separation technique of environmental analysis has been capillary GC combined with MS or with specialized GC detectors such as the flame ionization detector and the electron capture detector, or more recently combined with liquid chromatography or capillary electrophoresis (LC-MS or CE-MS). In recent decades, the introduction into commerce and the environment of increasingly polar and nonvolatile compounds has resulted in new interest in liquid separations for environmental problems, resulting in the growth of liquid separation methods of analysis, and it is especially useful for polar or thermally labile compounds or for nonvolatile high relative molecular mass compounds. The following discussion is organized by type of separation technique or other analytical technique rather than by compound type.

The most common application of electronic spectroscopy has been as the detection technique for liquid separations where absorption spectroscopy is the workhorse technique. Absorption spectroscopy is well suited for liquid separations because most of the solvents of choice exhibit large UV transparent regions that enable the sensitive detection of compounds of interest. This is in contrast to other types of detectors that might universally detect both the solvent and the analyte of interest. For example, infrared detection is often compromised by the presence of either water or other solvents because of strong absorptions that obscure key portions of the useful wavelength range. Even mass spectrometry requires special interfaces to remove the solvent preferentially before introduction into the ion source even though solvent molecular masses are generally below 100 Da.

The detection limits for absorption spectroscopy are approximately 1×10^{-5} absorption units (AU), varying with the extinction coefficient as a function of wavelength. (The absorption measured in AU is defined as the common logarithm of the initial to the final light intensity.) This results in detection limits in the ppm to low ppb range in favourable cases, providing sensitivity adequate for environmental analysis. In fluorescence detection, the possibility of detecting a single molecule exists. For environmental samples, often fluorescing interferences limit the sensitivity and in these cases pretreatments or liquid separations remove these interferences. In practical terms, fluorescence detection for appropriate molecules can be 100 to 1000 times more sensitive than absorption detection. As a result, detection limits in the low parts per trillion range can be achieved for selected analytes, limited only by excitation source intensities or fluorescence from capillary or solvent background fluorescence.

HPLC

The most widely used detection technique for HPLC involves absorption at either a fixed wavelength or using a DAD that allows for wavelength selection and continuous or selected scans. In the filter photometric format, a wavelength such as 220 nm is selected by means of a filter placed in front of the deuterium lamp. **Figure 1** illustrates the detection of a series of polynuclear aromatic (PNA) compounds using their absorption at 220 nm. Common solvents used in reversed-phase separations (i.e. a hydrophobic adsorbent with water/organic solvent as mobile phase) have UV transparency from ~ 200 nm on up. A similar situation holds for normal phase separation (i.e. a polar adsorbent with hexane/polar solvent as mobile phase) where UV transparency is counted on. When the solvent choice includes toluene or some other absorber then a different wavelength or different detection technique must be chosen.

When a DAD is used, a selection of wavelengths may be available for individual monitoring as well as the selection of the best wavelength for quantitation in consideration of background noise that may be largely chemical noise or interferences from the matrix. In the case of PNAs, the full absorption spectrum for benzo[*a*]pyrene is given in **Figure 2**.

Molecules that do not possess the appropriate chromophore may be detected when derivatized with a chromophore with high extinction coefficients at peaks in the visible spectrum to facilitate detection. For example, carboxylic acids can be derivatized with 7-methoxy-4-bromomethylcoumarin to give them a chromophore. Specialized books may be consulted for further information concerning derivatization. Other techniques include resorting to wavelengths below 200 nm under special conditions. In some cases, indirect detection can be used based on the presence of a background UV absorber in the mobile phase. The analyte displaces some of this absorber under certain conditions, resulting in a decrease in the absorption level in the detector cell

Figure 1 HPLC separation of PNAs with detection by absorption spectroscopy at 220 nm.

Figure 2 HPLC separation of selected pesticides with DAD with a full absorption spectrum (200 to 600 nm) illustrated for each in a three-dimensional format.

Figure 3 HPLC separation of selected PNAs using fluorescence detection with excitation at 325 nm (xenon lamp) and emission at 425 nm.

which can be measured in the same manner as an increase in absorption. Further information on this technique can be obtained from specialized references on the subject.

When the analyte of interest possesses fluorescence character then an extremely sensitive detection can be designed based on the absorption/emission properties of the molecule. In **Figure 3**, the fluorescence detection of benzo[*a*]pyrene is illustrated using an excitation of 325 nm with an emission at 425 nm. In this manner, low pg quantities of compound can be detected, making this one of the most sensitive detections in analytical chemistry. Increasingly, charged coupled devices (CCDs) are being utilized to give even higher sensitivity especially with laser excitation, and whole spectra rather than single wavelengths are being recorded. Techniques such as fluorescence lifetime detection with phase or frequency modulation can also be used to separate peaks that would otherwise appear to overlap.

Capillary Electrophoresis (CE)

CE has emerged as a pre-eminent separation technique for ionic analytes based on free zone electrophoresis. The separation is based on differing mobilities among the ions. In analogy to HPLC, an absorption detection is a fairly universal detector. The DAD response for a group of phenols is illustrated in **Figure 4**. The influence of ionization on the absorption spectrum of phenols is evident in the shift to longer wavelengths that results from the anionic character. One of the chief drawbacks of CE applications using absorption detection has been the relatively high concentration detection limit (i.e. ppm range rather than ppb range of HPLC). This is a direct result of the capillary format of the separation. In capillary separations, normally tens of nanolitres of sample are injected on-column. This is a 1000-fold smaller volume than in HPLC. In addition, the capillary format usually demands on-column detection to avoid band broadening from post-column detection approaches. The

Figure 4 DAD detection of phenols in capillary electrophoresis. The arrow indicates the wavelength position of 298 nm.

Figure 5 CE-LIF detection of phenols using a frequency-doubled laser. Excitation at 244 nm and emission at 355–425 nm. The arrow indicates the migration time position of 12.257 min.

diameter of the capillary is about 75 μm , resulting in a very short optical path. There are specialized techniques for overcoming these limitations and more specialized references should be consulted.

The concentration detection limit problem can be overcome for molecules possessing fluorescence. In the case of phenols, illustrated in **Figure 5**, a frequency-doubled laser operating at 244 nm will enable sensitive detection using laser-induced fluorescence (LIF). In this case, a filter arrangement allows detection of emission light in the 355 to 425 nm range. The use of lasers in this context improves detection limits because of the light intensity as well as the intrinsic narrow beam which allows efficient focussing of the light onto the capillary bore carrying the sample.

Figure 6 CE-LIF detection of probe peak (fluorescein-labelled 2,4-dichlorophenoxyacetic acid) in an immunoassay format of herbicide analysis. Excitation at 488 nm and emission at 510–530 nm.

Immunochemical Analysis

Immunochemical analysis is a convenient approach for environmental analysis provided appropriate antibodies and format have been developed. Often, the assay depends on a colorimetric determination for its quantitative result. The advantage of immunochemical analysis is its specificity as well as its speed. Specific references should be consulted on applications.

An emerging format for the assay depends on CE-LIF determination of a fluorophore-labelled analyte (probe) in either a competitive or a noncompetitive assay with the unlabelled analyte as they find binding sites with the antibody. **Figure 6** illustrates the concept for a fluorescein-labelled analogue of 2,4-dichlorophenoxyacetic acid (2,4-D) where the change in the amount of the probe peak indicates whether unlabelled 2,4-D was present in the sample.

Gas Chromatography

One detection technique for GC, called an atomic emission detector (AED), is of fairly common occurrence and makes use of spectroscopic properties for detection. The elements of a compound that elutes from the column are determined in a He plasma based on the emission spectra of the individual elements (e.g. C, H, O, N, S, Cl, etc.). Reference to more specialized works should be made. The AED technique is mentioned for the sake of completeness, although since AED relies on atomic spectroscopy emission, it is outside the scope of

this article, which is mostly restricted to molecular electronic spectroscopy.

Thin-Layer Chromatography

Thin-layer chromatography (TLC) is usually coupled to either absorption or fluorescent detection of complexed species and is common in many fields of analysis. The applications of TLC to environmental analysis have been less frequent than with other forms of separation. It has recently been demonstrated that UV-visible absorption, near-IR absorption, fluorescence, and phosphorescence can be accomplished for hundreds of spots on a single TLC plate by using CCD detection.

Emerging Techniques

The application of molecular electronic spectroscopy as a detector for separations is expected to continue to grow. Optical techniques are a primary detection approach for the hybrid technique of capillary electrochromatography which combines aspects of CE and HPLC, especially capillary LC. To increase throughput of sample handling, arrays of capillaries have been built with optical detection via CCD cameras. Using CE-LIF approaches, hundreds of capillaries can operate simultaneously on samples with simultaneous detection. Further advances are expected in the areas of remote sensing, immunochemical assays, capillary arrays, and detector sensitivity.

Introduction

The basic requirement for an EMRI experiment is that a species having unpaired electrons be present. Although free radicals and some transition metal compounds fulfil this requirement, there are not many circumstances in which these are present naturally in sufficient concentration to give a suitable signal; this is in contrast to MRI where the ubiquitous proton can be used to study most materials. Fortunately, the high sensitivity of EPR compared with NMR (arising from the difference in electron and nuclear magnetogyric ratios) enables paramagnetic material to be introduced in low concentrations into systems under investigation with minimum interference. However, NMR has an advantage over EPR in that pulse techniques can be used to boost the signal-to-noise ratio: both the irradiating frequency and the applied magnetic field gradients can be pulsed. The main reason why most EPR experiments are carried out in the continuous-wave (CW) mode is because spin–lattice relaxation times for paramagnetic materials are of the order of microseconds (compared with hundreds of milliseconds for proton NMR) and this causes considerable difficulties in achieving the short times required for the pulse experiment. A further difficulty is the spectral bandwidth of an EPR spectrum: this, coupled with a large line width (three orders of magnitude greater than in NMR) means that very large magnetic field gradients (100–1000 times greater than in MRI) have to be applied. However, for the few systems not presenting these difficulties, FT-EMRI will become the method of choice. The ability to employ pulse techniques for both the irradiating frequency and for the field gradients also allows a much wider variety of experiments to be carried out with MRI compared with EMRI.

Spin Probe

The paramagnetic materials added to systems to obtain signals in EMRI are referred to as spin probes. These can be transition metal compounds such as those of manganese(II) or vanadium(IV) but they are more likely to be organic free radicals. In addition to having high thermal, chemical and metabolic stability (for biological applications), these radicals should preferably have spectra

with very narrow line widths in order to maximize the signal-to-noise ratio. The peak-to-peak line width of a first-derivative spectral line can be represented by the equation:

$$\Delta B_{pp}(m_1) = A + Bm_1 + C(m_1)^2$$

where A , B and C are constants and m_1 is the magnetic quantum number of a given line. The constant A is dependent on the g factor anisotropy and experimental factors, B upon the g factor and the nuclear hyperfine interaction anisotropies and C upon the nuclear hyperfine interaction anisotropy. EPR spectra are normally recorded in the first-derivative mode but, obviously, the absorption mode is more convenient for EMRI. The most common stable free radicals used as spin probes are nitroxyls and there is both g factor and hyperfine interaction anisotropy of the ^{14}N nucleus. A typical set of values at X-band for a nitroxyl radical having unresolved proton hyperfine structure is $A = 0.116$, $B = -0.010$ and $C = 0.006$ mT. Thus the observed line width is of the order of 0.1 mT and there is little scope for reducing the line width further for imaging at X-band: a nitroxyl radical in a nitrogen-purged low-viscosity solvent can show a resolution of proton hyperfine couplings with observed line widths smaller than 0.02 mT. The three lines of a nitroxyl radical, in addition to having a large bandwidth, also represent a ‘waste’ of signal since it is more practical to image a single line. Some improvement can be made by substituting ^{14}N with ^{15}N and/or by reducing the proton hyperfine interaction by deuteration. However, there is a soluble commercial single-line free radical based upon the $\cdot\text{C}(\text{Ar})_3$ structure which has a line width of only 0.006 mT in a deoxygenated solvent: the sharp line is observed because of the small g factor and hyperfine anisotropies for a carbon-centred radical. One of the main aims in biological studies is to spin-label drugs and to image their organ compartmentation, and hence there are some difficult chemical problems to be solved. For some studies, it is possible to use solid particles as spin probes in which case very narrow single lines are attainable. An example is lithium phthalocyanine which has a line width of 0.002 mT in a deoxygenated system. Other single-line solids are special forms of coal, such as fusinite, and carbohydrate chars.

Theory

Resonance imaging depends on the application of magnetic field gradients to a sample. If two samples are placed at different positions of the spectrometer magnetic field then only one of them will be at resonance, the second one can be brought to resonance by changing the spectrometer field or by applying a magnetic field gradient. Since field gradients can be applied in three dimensions, it is possible to determine the relative positions of both the samples, i.e. to produce an image. Mathematical methods are of central importance in any type of image reconstruction and they were developed some time ago for radiographic tomography. The necessity of using CW techniques in EMRI limits the number of imaging strategies that can be employed.

Spatial Imaging

Two-dimensional images of spin density in the xz or yz planes (z axis is parallel to the main magnetic field) can be obtained: for an $n \times n$ image, $n\pi/4$ projections are required. Most spatial images of paramagnetic centres with multiline spectra have been constructed by selecting a single line, using a limited field gradient to avoid overlap with other lines. The resolution can be enhanced by deconvolution of the line shape.

Spectral-Spatial Imaging

The advantages of spectroscopic imaging compared with spatial imaging methods are:

- (i) the problems of resolution and gradient magnitudes owing to the presence of hyperfine lines can be overcome;
- (ii) separating spectral and spatial components by assigning them to different imaging axes reduces the resolution degradation arising from the finite width of the spectral lines;
- (iii) asymmetric and multiline spectra can be imaged, whereas only symmetric line shapes should be used for spatial imaging.

Images are obtained as a function of sample position by recording spectra at a series of magnetic field gradients which correspond to projections in the spectral-spatial plane. A pseudo-object of length B is examined in the spectral dimension and length L in the spatial dimension. An angle (α) defines the orientation of a projection relative to the spectral axis. The maximum field gradient, $G_{\max}$, is related to B and L by

$$G_{\max} = \tan(\alpha_{\max})B/L$$

The maximum magnetic field swept for each projection is given by

$$\text{Sweep width} = 2^{1/2} B \cos \alpha$$

For given values of $G_{\max}$ and B the ratio $\tan(\alpha_{\max})/L$ is fixed. Most image reconstruction algorithms require projections over 180° with equal angular increments. If a complete set of projections is used for spectral-spatial imaging, the number of projections determines the values of $\alpha_{\max}$ and $G_{\max}$. Thus for 64 projections, $L = 0.8$ cm and $B = 3.2$ mT, $\alpha_{\max} = 88.59^\circ$, $G_{\max} = 162.5$ mT and the sweep width required is 183.9 mT. Spectral-spatial images can be reconstructed from incomplete sets of projections and this has the advantage of reducing both the maximum field and sweep width requirements. Assuming experimental data were obtained for 60 out of 64 projections and estimates were made for the 'missing' projections, then $G_{\max}$ and the sweep width requirements are reduced to 32.4 and 37.0 mT, respectively.

Projection Reconstruction Methods

Important image reconstruction procedures are:

- (i) back projection;
- (ii) simultaneous, algebraic and iterative least-squares;
- (iii) two-dimensional and filtered back projection; and
- (iv) use of incomplete data sets from which it is also possible to obtain slices from the image.

Modulated Magnetic Field Gradients

These gradients, B_{GM} , provide fields in addition to the main magnetic field that have both time- and space-dependent amplitudes. The time-independent spectrum can only be recorded in the z plane where the amplitude of B_{GM} is zero. Images can be obtained without the use of difficult mathematical deconvolution by scanning the plane of the field gradient across the sample.

X-Band Imaging

Imaging at about 9 GHz is very convenient since most commercial EPR spectrometers operate at this frequency and the imaging system can be fitted as an accessory. Gradient coils can be fitted to the outside or to the inside of a standard resonant cavity. **Figure 1** shows the arrangement for the former: to generate sufficiently large gradients, ~ 1 kW of power is needed and hence provision for water cooling has to be made. **Figure 2** shows how small coils, used for microscopy, can be placed inside the cavity. X-Band frequencies can be used for non-polar samples up to 10 mm in diameter but polar samples are restricted to 1.5 mm diameter because of the absorption of the microwave energy. An estimate of the achievable

Figure 1 The arrangement of figure-of-eight (A) and anti-Helmholtz (B) coils fitted to the outside of a rectangular resonant cavity, to provide gradients $\delta B_z/\delta x$ and $\delta B_z/\delta z$ respectively.

resolution is a pixel of $10 \times 10 \times 10 \mu\text{m}$ that contains 1 mM spins. Note that the latter concentration cannot be increased appreciably without causing line broadening from spin-spin interactions.

An example of two-dimensional spectral-spatial imaging is shown in **Figure 3**. This depicts the projection-reconstruction image obtained from four different-sized specks of DPPH (diphenylpicrylhydrazyl), each of which gives an exchange-narrowed single spectral line. **Figure 4** is an example of a two-dimensional spectral-spatial image, showing a phantom that contains solutions of three types of free radicals which each have some hyperfine structure.

X-Band EMRI has been applied to the study of the diffusion and distribution of oxygen in models of biological systems with the aim of studying diffusion and metabolism *in vivo*. The method is based on the fact that oxygen causes paramagnetic broadening of the spin probe lines. Other applications have been (i) for the determination of depth profiles of E' defects in X-irradiated silica, (ii) for radiation chemistry, where a dosimeter has

Figure 2 (a) A cylindrical EPR cavity fitted with anti-Helmholtz coils and a PTFE sample holder. The test sample comprises two portions of DPPH powder separated by a $50 \mu\text{m}$ mylar film. been designed using crystalline L- α -alanine which can be used to check the spatial variation of the radiation, (iii) a variation of this theme to study the distribution of alkyl and alkoxy radicals in γ -irradiated polypropylene, (iv) to study diffusion and transport of nitroxyl radicals, for example into zeolites, into solid polymers and into the caryopsis of wheat seeds and (v) to study paramagnetic humic substances found in soil. **Figure 5** shows an image obtained from the soaking of these into a wheat grain.

There are several strategies for EMRI microscopy, and an example is shown in **Figure 2**. Arrangements of this type are capable of giving a resolution of $50 \mu\text{m}$. EMRI microscopy can be used for (i) small-scale dosimetry of materials exposed to high-energy radiation, (ii) ceramic and semiconductor technology and (iii) the distribution of nitrogen centres in diamonds.

L-Band Imaging

Most current biological imaging systems operate at L-band frequencies ($\sim 1 \text{ GHz}$) which allow larger and more 'lossy' samples to be studied (microwaves of this energy can penetrate about 6 mm into a biological specimen) than is possible at X-band. A fairly standard spectrometer can be adapted for this work but loop-gap

resonators, external surface coils and re-entrant cavities are more useful than a standard resonant cavity.

A non-biological application of L-band EMRI has been the study of the oxidation of cylindrical coal samples at 150 °C where it was found that there is a homogeneous distribution of radicals across the samples. An important biological application is the study of oxygen concentrations ('oximetry') in a perfused rat heart using implanted solid paramagnetic particles: this rapid (1–5 min) multisite *in vivo* spectroscopy can be applied to a wide range of problems in experimental physiology and medicine. Other biological applications involve the imaging of soluble free-radical distribution: some examples include (i) a three-dimensional image of the head of a living rat, showing that the nitroxyl-deficient part corresponds to the brain, and (ii) accurate images of the vessel lumen and wall of a perfused rabbit aorta. When a glucose char (having a single EPR line) is introduced into an isolated biological organ, the resolution obtainable is 0.2 mm (Figure 6) whereas a soluble nitroxyl spin probe allows a resolution of only 1–2 mm. The single-line soluble probe $^*C(Ar_3)$ has allowed images of a rat kidney to be visualized with a resolution of 100 μ m for samples up to 25 mm. As in MRI, data acquisition can be gated to overcome the problems associated with rapidly moving organs such as a beating heart.

A biologically important naturally occurring free radical is nitric oxide but, unfortunately, it has very broad EPR lines and thus cannot be imaged. However, its generation in rat hearts subjected to global ischaemia has been

mapped by using the spin trap bis(*N*-methyl-D-glucamine dithiocarbamate)iron(II). The latter forms a stable nitroxyl free-radical with nitric oxide that can be imaged.

Four-dimensional spectral-spatial EMRI has been developed (1000 projections were used to construct $32 \times 32 \times 32 \times 32$ pixel images) and, while considerable data acquisition times are needed, it is feasible to obtain spectral information for a biological structure such as a rat heart.

High-Field Imaging

A high-field imager using a superconducting magnet operating at 5 T (140 GHz) has been constructed that derives its very large field gradients from ferromagnetic discs and wedges. This type of instrument is aimed at studying processes that have spatial ranges of less than 10 μ m such as diffusion, defect formation in irradiated samples and polymer fracture under stretching and loading. High spectral resolution can be achieved because of the high absolute point sensitivity. A commercial EPR spectrometer is available for W-band (95 GHz) that can be adapted for high-field EMRI.

Radiofrequency Imaging

It has been stated above that it is difficult to obtain images at L-band frequencies of lossy objects larger than

Figure 6 Three-dimensional images ($25 \times 25 \times 25$ mm³) of an ischaemic rat heart infused with a glucose char suspension. (a) Full view of the heart. 25 mm. Thus to image large samples, such as live animals, lower frequencies have to be used. There is also an added incentive to work at radiofrequencies because of the low cost of components compared with those used at microwave frequencies. The consensus of opinion is that the most suitable frequency is about 300 MHz, which has a penetration depth of about 7 cm in systems of high relative permittivity. Theory suggests that the signal-to-noise ratio and resolution of EMRI are very much worse than they are for MRI. However, the high point sensitivity of EMRI compared with MRI provides advantages for probe experiments and thus EMRI should include, at some level, a spectral dimension. At radiofrequencies the line widths of nitroxyl spin probes are similar to those at X- and L-bands since the dominant factor for these probes is the anisotropic hyperfine interaction which is field independent. It should be noted that, for nitroxyls, account has to be taken of the Breit–Rabi effect. As might be expected, the experimental approach has features in common with MRI; for example, ‘bird-cage’ resonators can be used. Other useful types of resonators are surface coils, re-entrant cavities and loop-gap resonators. The main magnetic field required for 300 MHz is about 11 mT, which can be obtained from a simple air-cored Helmholtz design. Because a non-ferrous magnet is used, the main field windings can also be used for modulation at a frequency of about 4 kHz. The x , y and z gradient coils can be wound on concentric cylinders and an advantage of the bird-cage resonator is that it can be mounted concentrically inside the cylinder, whereas a loop-gap resonator would have to be mounted across the cylinder making sample access more difficult. A bird-cage resonator has been used to implement longitudinally detected EPR, which has the advantage of giving less noise from animal motion. The latter can also be minimized by automatic frequency control of the radiofrequency. A multipole magnet has been constructed which allows the main field and two of the gradient fields to be generated; the third gradient is obtained by inserting an air-cored coil into the magnet. In another design, two Helmholtz loops are splayed to produce the z direction field gradient.

A variety of studies using RF EMRI have been carried out on living mice. These include (i) oximetry in tumour tissues and the response to perfluorocarbons for their potential use in radiotherapy, (ii) the detection of hydroxyl radicals (by spin trapping) in γ -irradiated tumours, (iii) the distribution of nitroxyl radicals with distinct pharmacological abdominal compartment affinities and (iv) quantitative measurement of the viscosity of a non-vascular compartment.

Methods of RF-based EPR imaging continue to be introduced, and examples include the development of a loop resonator for imaging live rats at 300 MHz by

employing a nitroxyl spin probe, three-dimensional imaging methods, four-dimensional spectral-spatial methods and new data processing methods.

The biomedical applications are proliferating. For example a comparative study of tissue redox-status imaging using commonly used redox-sensitive nitroxides has been carried out using EPR imaging, Overhauser magnetic resonance imaging (OMRI, see the next section) and conventional T1-weighted magnetic resonance imaging (MRI). Another application used an EPR system operating at low frequency, to record *in vivo* EPR spectra and images from the melanin present in a subcutaneous melanoma implanted in a mouse. An interesting study showed EPR oxygen images obtained from the legs of mice bearing fibrosarcomas under both normal (air breathing) and clamped tumour conditions. The tumours were irradiated at the dose at which 50% of tumours could be cured. Tumour tissue was distinguished from normal tissue using co-registration of the EPR oxygen images with spin-echo MR images of the tumour. The analysis of the tumours demonstrated that tumour cure correlated with dose and the resulting hypoxic nature of the tissue. The results showed that, together, radiation dose and EPR image-derived hypoxic fraction separate the population of fibrosarcomas that are cured from those that fail, thus predicting curability.

Overhauser Imaging

The broad lines encountered in EPR lead to poor spatial resolution compared with MRI and hence it is unlikely that a whole-body human-size imager is possible using the techniques described above. There is, however, an imaging strategy that could lead to a large-sample imager by taking advantage of the Overhauser effect – techniques using the effect are also known as PEDRI (proton–electron double resonance imaging) and DNP (dynamic nuclear polarization) imaging. This is done by using a double resonance technique in which low-field proton MRI is combined with EPR. The EPR spectrum of a free radical is irradiated during the collection of a proton NMR image. The Overhauser effect produces an enhancement (by a factor of about 100) of the NMR signal in the parts of the sample that contain free radicals. The big advantage is that MRI resolution is achieved without having to use large field gradients but the disadvantage is that spectral information cannot be obtained. To overcome this drawback, an instrument has been constructed that combines Overhauser imaging with EMRI. In Overhauser imaging, an EPR frequency lower than 300 MHz has to be used to avoid heating of a biological sample. When nitroxyl spin probes are being used it is possible to irradiate each of the three ^{14}N manifolds

simultaneously to achieve a maximum Overhauser enhancement. Resonators are similar to those used in radiofrequency imaging, namely loop-gap or bird-cage structures. Normally, an MRI image is obtained and subtracted from an Overhauser MRI image for the slice under study. This is done by using an interleaved pulse sequence, each alternate NMR excitation being preceded

by EPR irradiation. An example of images obtained in this way is shown in **Figure 7**.

By cycling the main magnetic field, large samples can be imaged by reducing the EPR frequency required to about 60 MHz without impairing the NMR signal-to-noise ratio. Most of the applications of Overhauser imaging are similar to those given above for radiofrequency

Figure 7 Set of proton Overhauser images from the abdomen of a supine, 350 g, anaesthetized rat, following the administration of a solution of hydrogencarbonate-buffered 3-carboxy-2,2,5,5-tetramethylpyrrolidine-l-oxyl (PCA). Image matrix size 64×64 ; field-of-view, 10×10 cm; slice thickness, 2 cm; field strength, 10 mT; EPR irradiation frequency, 238.7 MHz. Image no. 1 was collected 1 min after administration of PCA and the remaining images were collected at 6, 11 and 16 min post-injection respectively. In: Grant DM and Harris RK (eds.) *The Encyclopedia of Nuclear Magnetic Resonance*.

imaging except that it is possible to study much larger samples. Oximetry, however, is carried out differently since it is possible to measure quantitatively the reduced Overhauser enhancement caused by the oxygen. An interesting aspect of Overhauser imaging is that it can be carried out at fields as low as that of the earth, i.e. 0.06 mT. The reason is that the enhancement is still high for magnetic fields lower than the hyperfine coupling of the spin probe, ~ 1.5 mT (70 MHz) for nitroxyl radicals. Thus it is possible to build an imager having a main field of about 0.3 mT that is regarded as biologically safe, is protected against magnetic perturbations and is of low cost.

Symbols

A	hyperfine coupling constant
B_0	static magnetic field
B_1	microwave magnetic field
B_2	radiofrequency magnetic field
g	electron g factor
h	Planck's constant
H	Hamiltonian operator
I	nuclear spin operator
k	Boltzmann constant
m_l	nuclear spin angular momentum
m_s	electron spin angular momentum
N_{-}	populations of electron energy levels separated by a magnetic field
N_{+}	
Q	quality factor of a resonator
S	electron spin operator
T	absolute temperature
T_1	longitudinal (spin–lattice) relaxation time
T_2	transverse (spin–spin) relaxation time
η	filling factor of a resonator
λ	microwave wavelength
μ_B	Bohr magneton
ν	microwave frequency
ν_n	nuclear Larmor frequency
τ	delay in pulse sequence

Introduction

Electron paramagnetic resonance (EPR) is also known as electron spin resonance (ESR) or electron magnetic resonance (EMR) spectroscopy; no single name has become generally accepted. It is a means of investigating materials that are paramagnetic, i.e. having unpaired electrons. These include organic free radicals, compounds of transition metal ions and defects in solids. Since the development of the X-band continuous-wave spectrometer in the 1950s and 1960s, the basic design of the EPR spectrometer has remained relatively unchanged, while a wide variety of applications in physics, chemistry and biochemistry have been devised. Examples are the observation of radical intermediates in chemical reactions; the determination of electron density distributions on radicals; the observation of rapid motion of spin labels in solution; and the determination of

coordination geometry of metal ion sites. Advances in solid-state microwave electronics have led to instrument extensions in many different ways, for specialist applications. Examples are ENDOR and TRIPLE and ESEEM, to measure hyperfine interactions, and low-frequency EPR imaging.

The principles of typical applications will be described, with reference to the relevant equipment and sample requirements.

Characteristics of the EPR Spectrum

EPR involves the interaction of electromagnetic radiation, usually in the microwave region, with the paramagnetic material in a magnetic field. Because paramagnetic centres are less common than nuclear spins, the method is more selective than the analogous technique of NMR. There are some differences in practice between NMR and EPR that result from the much greater magnetic moment of the electron compared to that of nuclear spins. The bandwidth of the spectrum is much greater than the parts-per-million scale of NMR. It is impossible to adjust the frequency over such a wide range, owing to the geometry of microwave waveguides, so it is the usual practice to observe the EPR spectrum at fixed frequency by sweeping the magnetic field. The relaxation rates of electron spins are faster than for nuclear spins, so that in some cases (particularly transition metals such as iron) it is necessary to cool the sample to cryogenic temperatures to observe the spectrum.

The spectrum is characterized by a number of parameters which give information about the nature of the paramagnetic centres and their surroundings.

Zeeman Interaction

The g factor defines the energy of the Zeeman interaction. This splits the energy levels of the paramagnet (Figure 1). At the resonance condition the energy ΔE required to reverse the direction of the electron spin in a magnetic field B_0 is equal to the energy of the microwave quantum $h\nu$, given by

$$\Delta E = h\nu = g\mu_B B_0$$

Figure 1 (a) Principle of electron paramagnetic resonance. (b) Effect of hyperfine splitting with a nucleus, $I = 1/2$.

where h is Planck's constant and μ_B the Bohr magneton. In an EPR spectrum the signals are obtained by increasing the B_0 field. The g factor is inversely proportional to B_0 .

For a free electron in a vacuum, g is a constant that is very precisely known ($g_e = 2.002\,319\,3044\dots$). In a paramagnetic molecule, g varies from this, under the influence of spin-orbit interactions. These increase considerably with atomic number, and are particularly important for lanthanides. In the spin Hamiltonian formalism the effects of spin-orbit coupling are described by treating g as a spectroscopic variable, the 'spectroscopic splitting factor', which is characteristic of the paramagnetic centre. Therefore the EPR spectrum may be considered as a spectrum of g factors.

Hyperfine Interaction

The interaction between the magnetic moment of the electron and nuclear spins is a valuable feature of EPR spectra. It introduces splittings of the electron energy levels (Figure 1b). Each nuclear spin I induces a splitting into $[2I + 1]$ levels. The magnitude of the splitting is

defined by the hyperfine coupling constant, A , which is expressed in energy units (usually MHz). Where there are several nuclei, for example protons in a radical, each level is further split by each nuclear hyperfine interaction. The hyperfine coupling can be observed as splitting of the EPR spectrum, if the coupling is greater than the line width. The magnitude of the splitting is given the symbol a , expressed in magnetic field units.

The value of A depends on the nuclear moment, and the extent of interaction of the unpaired electron spin density with the nucleus; A has a sign as well as magnitude. If $A > 0$, the state in which electron and nuclear spins align antiparallel is of lower energy. Measurements of the magnitude and sign of hyperfine couplings provide some of the most detailed experimental evidence for electronic structures of molecules. They have been used to verify the results of molecular orbital calculations.

In EPR spectra of transition ions, the hyperfine interaction gives rise to characteristic splittings, for example for copper ($I = \frac{3}{2}$, 4 lines) and manganese ($I = \frac{5}{2}$, 6 lines) (Figure 2a). It can be used to identify paramagnetic centres and determine the electron density distribution over radicals. Isotopic substitution can be used (Table 1) to identify specific metals, for example ^{57}Fe for natural iron. Interactions with nuclei of ligands, sometimes called superhyperfine splittings, allow the determination of the electron density distribution in transition metal complexes. Nuclei with spins greater than $S = \frac{1}{2}$ have a quadrupole moment and this gives rise to further splitting of the energy levels.

Interactions between Electrons (Fine Structure Interactions)

The magnetic moment of the electron is 658 times that of the proton, so that interactions between electrons are of greater energy than those between nuclear spins, and are detectable over greater distances. This has a number of consequences. For example, when two or more electron spins are present in a paramagnetic centre such as a transition ion with spin $S > \frac{1}{2}$ or an organic triplet state ($S = 1$), coupling of the electron spins gives rise to fine structure splittings (known as zero-field splittings) which strongly influence the apparent g factor. If the spin is an integral value, the splitting between the energy levels may be larger than the X-band microwave quantum, and no EPR signal is detected. However, for an odd number of electron spins there are always energy levels that can only be split by the magnetic field. As a consequence paramagnets with half-integral spin, such as high-spin Fe^{III} and Co^{II} , are EPR-detectable (see Figure 2b). For the latter ions, with $S = \frac{5}{2}$, g factors may extend from 10 to 0. EPR spectra of transition ions are often measured in

Figure 2 EPR spectra of transition ions; (a) manganese ions in aqueous solution; note the six-line hyperfine splitting owing to the ^{55}Mn nucleus ($I = \frac{5}{2}$); (b) high-spin Fe^{III} in metmyoglobin, frozen at 77 K; note the g factors at 6.0 and 2.0.

Table 1 Some nuclei with magnetic moments

Isotope	% Natural abundance	Nuclear spin, I	μ_N
^1H	99.985	$\frac{1}{2}$	+2.793
^2H	0.015	1	+0.857
^{13}C	1.11	$\frac{1}{2}$	+0.702
^{14}N	99.63	1	+0.404
^{15}N	0.37	$\frac{1}{2}$	-0.283
^{17}O	0.037	$\frac{5}{2}$	-1.89
^{19}F	100	$\frac{1}{2}$	+2.629
^{31}P	100	$\frac{1}{2}$	+1.132
^{33}S	0.76	$\frac{3}{2}$	+0.643
^{55}Mn	100	$\frac{5}{2}$	+3.444
^{57}Fe	2.19	$\frac{5}{2}$	+0.090
^{59}Co	100	$\frac{7}{2}$	+4.649
^{63}Cu	69.09	$\frac{3}{2}$	+2.226
^{65}Cu	30.91	$\frac{3}{2}$	+2.385
^{95}Mo	15.72	$\frac{5}{2}$	-0.913
^{97}Mo	9.46	$\frac{5}{2}$	-0.933

the solid state so that the spectrum is broadened by anisotropy of the g factor.

Electron spin–spin interactions occur between paramagnetic centres in solution and in the solid state. This causes splitting or broadening of the EPR signal. For solid paramagnetic materials the broadening may be so great

as to render the X-band EPR spectrum undetectable. For EPR spectra in the solid state, the material must usually be *magnetically dilute*, for example doped into a diamagnetic host material. Paramagnets in biological materials such as proteins are usually fixed within the protein matrix and are thus detectable. Spin–spin interactions give rise to characteristic changes in line shape, and enhancement of the electron-spin relaxation rate, from which it is possible to estimate distances between the paramagnetic centres.

Anisotropy

The Zeeman, dipolar hyperfine and fine structure interactions are all anisotropic, meaning that the energy of interaction depends on the angle between the paramagnetic centre and the applied magnetic field. In solution spectra of small molecules, the anisotropy is averaged, and spectral lines are narrow. Note, however, that the isotropic hyperfine interaction does not average to zero and so there is still hyperfine splitting (e.g. **Figure 2a** and **Figure 3a**). For randomly oriented samples in the solid state (so-called powder spectra), the distribution of molecules in different orientations gives rise to characteristic broadening of the line shape (**Figure 2b** and **Figure 3c**).

Effects of Temperature, Electron-Spin Relaxation and Spectral Linewidths

Temperature has a number of effects on the EPR spectrum. The populations of the electron energy levels N_- and N_+ (**Figure 1a**) differ by a small amount because of the Boltzmann distribution:

$$\frac{N_+}{N_-} = \exp\left(\frac{\Delta E}{k_B T}\right) = \exp\left(\frac{g\mu_B B_0}{k_B T}\right)$$

where k_B is the Boltzmann constant and T the absolute temperature. At room temperature and a magnetic field of 0.32 T, the difference is about 0.07% of the unpaired electrons. It increases at higher microwave frequencies (hence higher fields), and at lower temperatures.

The spin–lattice relaxation, with a characteristic time T_1 , is responsible for maintaining the population difference between levels N_- and N_+ . The spin–spin relaxation time T_2 reflects the lifetime of the excited state and its effect on the line width. If the electron–spin relaxation rate is too rapid, the lifetime of the excited state is short and the EPR spectrum becomes broadened. At high temperatures the spectrum may become too broad for detection, hence the use of cryogenic temperatures for some transition ions. However, if the spin–lattice relaxation is too long, the population difference $N_- - N_+$ cannot be maintained, and the amplitude of the signal is attenuated, a situation known as microwave power saturation. Electron–spin relaxation times may be estimated by measuring the amplitude of the signal as a function of applied microwave power.

Operation of the Spectrometer

The outline of a conventional continuous-wave EPR spectrometer is shown in **Figure 4**. The term ‘continuous-wave (CW)’ refers to the fact that microwaves are applied throughout the measurement. It is designed to optimize the weak EPR signals originating from the sample, against a background of noise from the source. The microwave source is a reflex klystron (a type of thermionic valve) or a Gunn diode (a semiconductor device). The detector is a microwave diode. The operating frequency is typically in the X-band (~ 9.5 GHz). This frequency is a compromise; higher frequencies increase the ratio $N_- : N_+$ (and hence sensitivity) but require smaller cavities and thus smaller sample size (and hence number of spins being measured). A typical sample volume is of the order of 0.1 cm^3 .

The microwave circuit is known as the microwave bridge, to emphasize that it is a balanced circuit. The source is tuned to the resonant frequency of the cavity. Microwaves pass through waveguides to the cavity via a circulator, which ensures that signal arising from the sample in the cavity passes to the detector. The reference arm serves to balance the signal with the input microwave power. The circuit is optimally tuned by matching its impedance with the cavity using the iris, to a condition known as critical coupling. In this situation the intensity of the microwave field B_1 at the sample is enhanced by the Q -factor of the cavity, typically several thousand-fold. When electron paramagnetic resonance occurs in the sample, a small amount of power is transmitted to the detector and is amplified and recorded.

The homogeneous B_0 field is provided by an electromagnet. EPR spectra are obtained by modulation of the field by a small amount, at a frequency of 100 kHz. A lock-in amplifier detects the EPR signal in phase with the modulation. Modulation and phase-sensitive detection is a standard method of noise rejection and enhances the signal-to-noise ratio, and hence the sensitivity of the technique, by as much as 10^5 . It gives rise to the characteristic first-harmonic (first-derivative) line shape. Although the absorption spectrum could be derived from this by integration, spectra are usually retained as the derivative form as it emphasizes narrow hyperfine splittings and other features.

Temperature Control

The form of the paramagnetic material may be solid, liquid or gas, and so appropriate temperature control of the sample is needed. The temperature of the sample may be controlled by flowing gas through a quartz vacuum jacket. For low temperatures, helium is used. The sample may be held in a Dewar of liquid nitrogen or helium. For smaller resonator designs such as loop-gaps,

Figure 4 Outline of a typical continuous-wave EPR spectrometer.

the whole resonator is immersed in a cryostat containing helium or nitrogen.

Resonators

The quality, or Q factor, of the microwave cavity or resonator is a measure of its efficiency at concentrating microwave energy. For a resonant a.c. circuit it is given by

$$Q = \frac{2\pi(\text{Energy stored})}{(\text{Energy dissipated per cycle})}$$

The filling factor η is the fraction of the microwave magnetic field B_1 which bisects the sample.

Two examples of resonators used in EPR are illustrated in **Figure 5**. Rectangular cavities [**Figure 5(a)**] are of metal which is coated with silver and gold for high conductivity. The sample is positioned at the maximum of the microwave magnetic field, B_1 . It may be irradiated with ultraviolet or visible light, in this example through a waveguide of length λ which prevents microwave leakage. The applied magnetic field B_0 is modulated with Helmholtz coils in the walls of the cavity. The B_0 and B_1 fields are oriented at right angles, which gives a maximum magnetic resonance interactions for $S = \frac{1}{2}$ paramagnets. For paramagnets with an integer spin, the resonant transition is forbidden in this geometry. Parallel mode cavities are used for this situation, in which B_1 is parallel to B_0 .

In the loop-gap resonator (**Figure 5b**), the coupling loop acts as an antenna to transmit microwave power to and from the bridge to the split-ring resonator element. The number of gaps is variable, depending on the sample size. The microwave magnetic field B_1 circulates in the ring, while the electric component is mostly confined to the gaps. Magnetic field modulation is also by external coils (not shown). Loop-gap resonators have better filling factors than rectangular cavities, so that the resonator can be smaller and the sample tube larger. They are particularly effective for lossy samples such as aqueous solutions.

Other designs of cavity are possible, including cylindrical resonators constructed of an inert dielectric material such as sapphire (alumina).

Computer Control and Data Acquisition

Most operations of the instrument are under computer control. The spectrum is recorded as a series of data points, along a linear axis of magnetic field. The signal-to-noise ratio can be improved by repetitive scanning and signal averaging. Fourier transform techniques are normally only used for analysis of pulsed EPR experiments. There is a range of different software for analysis of the spectroscopic data, in particular for simulation.

Sample Holders and Sample Preparation

The holders for EPR samples are constructed of a diamagnetic, nonconductive material such as quartz.

Figure 5 Resonators for EPR spectroscopy. (a) Rectangular cavity; (b) loop-gap resonator.

Electrically conductive materials such as metals cannot be used as they reflect microwaves and prevent penetration of microwaves into the sample.

It is not possible to measure EPR spectra of large aqueous samples at frequencies above 1 GHz because of microwave power losses. For measurements in an X-band rectangular cavity, specially constructed flat cells are used, with a thickness of about 0.3 mm (**Figure 6**). They are placed in the centre of the cavity, which is a nodal plane of the electric vector, hence minimizing dielectric losses.

Oxidation–reduction reactions are used to generate organic or inorganic compounds in their paramagnetic oxidation states, for example quinones in their semi-quinone states, or transition metal ions in their paramagnetic states (**Table 2**). Electrolytically generated radicals may be obtained by means of electrodes placed in the cell above and below the cavity.

For kinetic measurements, paramagnets may be generated by mixing solutions and flowing them into a cell inside the cavity (**Figure 6** (centre)). For short-lived states of transition metals in solution, samples may be obtained by rapid freezing, in which samples are mixed and squirted into a bath of isopentane at 140 K.

Multifrequency EPR

Although the majority of EPR spectra are still taken at X-band frequency, there are advantages for some applications to use lower or higher microwave frequencies, or a range of frequencies. To operate at each frequency it is usually necessary to use a different microwave bridge and cavity. These frequencies are identified by their frequency bands, as listed in **Table 3**.

Figure 6 Sample holders for aqueous samples.

In high-frequency spectrometers, superconducting magnets are used. Up to 100 GHz, the microwaves may be obtained by mixing with lower-frequency radiation in a heterodyne arrangement. For higher frequencies, the radiation may be regarded as far infrared, and Fabry–Pérot resonators are used which consist of two parabolic mirrors to concentrate the radiation. In low-frequency spectrometers the magnetic field is produced by Helmholtz coils and the resonator is a coil similar to that used in NMR.

Some features of the EPR spectrum increase with magnetic field, such as the separation between g factors. Others, such as the separation between hyperfine

splittings, do not change, to first order. By altering the microwave frequency it is possible to resolve the effects of multiple electron–nuclear and electron–electron interactions. The EPR spectra of organic radicals at X-band (9 GHz) are dominated by hyperfine splittings by protons and other nuclei. At W-band (96 GHz) the spectra are dominated by the anisotropy of the g factor.

Electron–Nuclear Double Resonance (ENDOR) and TRIPLE Resonance

The hyperfine interactions with nuclei adjacent to the paramagnetic centre are often too small to be observed because they are smaller than the EPR line width. Electron–nuclear double resonance is a technique which detects these interactions. In addition to the microwave field B_1 a radiofrequency field, B_2 , is applied at right angles. A commercial design uses a coil wound around the sample tube in a special cavity.

The energy levels and transitions relevant to the ENDOR measurement are illustrated in **Figure 7**. The microwave field, at the EPR resonant frequency, partially saturates the signal, equalizing the populations of the $m_s = \pm \frac{1}{2}$ levels. The radiofrequency is swept, and when the latter is at the resonant frequency of the interacting nuclear spins this provides further pathways for electron spin relaxation and the EPR signal is enhanced. The

resulting spectrum consists of a pair of lines. The positions of the lines depend on the relative magnitudes of the hyperfine coupling, A , and the nuclear Zeeman frequency, ν_n (the NMR frequency of the nucleus) (**Figure 7**). In the case where $\nu_n > A/2$, as for protons, which have a large nuclear moment, the lines will be centred at ν_n and separated by A . When $A/2 > \nu_n$ as in the case of strong couplings to other nuclei, the ENDOR spectrum consists of two lines centred at $A/2$ and separated by $2\nu_n$.

Hyperfine interactions of the order of a few megahertz can be resolved and provide information about nuclei at distances up to 0.5 nm. An additional advantage of ENDOR is that the number of lines is additive, rather than multiplicative. If there are numerous nuclear spins in the paramagnetic molecule, each type of hyperfine splitting will give just one pair of lines and so the ENDOR spectrum is simpler than the EPR spectrum. This feature is particularly useful in the interpretation of the complex spectra of radicals.

TRIPLE resonance is another method which resolves further a spectrum containing multiple hyperfine couplings. It is analogous to the Overhauser effect in NMR. By continuously applying radiofrequency radiation at the resonant frequency of one line in the spectrum, other lines in the ENDOR spectrum are suppressed or enhanced if they are connected to the same transition. This method makes it possible to determine the sign of A , which is used in molecular orbital calculations.

Table 2 Examples of paramagnetic transition ions

<i>Metal ion</i>	<i>Paramagnetic oxidation states</i>	<i>Other states</i>
Vanadium	V ^{IV}	V ^V , V ^{III}
Chromium	Cr ^{III} , Cr ^{VI}	
Manganese	Mn ^{II} , Mn ^{IV}	Mn ^{III}
Iron	Fe ^{III}	Fe ^{II}
Cobalt	Co ^{II}	Co ^I , Co ^{III}
Nickel	Ni ^I , Ni ^{III}	Ni ^{II}
Copper	Cu ^{II}	Cu ^I
Molybdenum	Mo ^V	Mo ^{IV} , Mo ^{VI}

Note – other oxidation states and isotopes exist for these elements.

Pulsed EPR

Pulsed EPR spectrometers are now commercially available and have some of the same electronic features as NMR spectrometers. The layout of the microwave bridge is similar to that of **Figure 4**, but in addition a pulse programmer controls the microwave supply through diode switches. The microwave pulses, of duration 5–50 ns, are amplified by a travelling-wave tube amplifier, to a power up to 1 kW. The cavity has a lower Q -factor

Table 3 Microwave wavebands and frequencies

<i>Band</i>	<i>Frequency (GHz) (app.)</i>	<i>λ (mm)</i>	<i>Field for $g = 2$ (mT)</i>	<i>Typical applications</i>
Radiofrequency	0.25	1200	8.93	EPR imaging
L	1	300	35.7	Aqueous sample EPR
S	4	75	143	Hyperfine splittings
X	9.5	31.6	339	Routine spectroscopy
K	24	12.5	857	
Q	35	8.6	1250	Electron spin–spin interactions
V	65	4.6	2322	
W	96	3.12	3430	g factor anisotropy in radicals
D	140	2.14	5000	Large zero-field splittings
G	250	1.2	8931	Even spin system

The definitions of bands follow EPR convention and the frequencies are approximate.

Figure 7 Energy levels for an electron interacting with an $I = \frac{1}{2}$ nucleus, showing the transitions relevant to ENDOR and electron-spin echo envelope modulation (ESEEM), (dotted lines).

than for CW EPR to allow the microwave field to build up more quickly. The main differences between pulsed EPR and pulsed NMR arise from the broad bandwidth of the EPR spectrum.

Flash Photolysis

For the spectra of radicals that are dispersed over a narrow range of frequency, it is possible to detect a free-induction decay (FID). This makes it possible to derive a spectrum by Fourier transformation and observe the spectrum of a transient species induced, for example, by a laser flash which is synchronized with the microwave pulse programmer (**Figure 8a**).

Normally, however, the spectrum is too broad, or the FID decays too rapidly. In this case it is possible to detect an electron-spin echo after a two-pulse ($\pi/2$ – π –echo) sequence. The spectrum of the flash-induced species is derived by repeating the measurement over a range of magnetic field strength. The lifetime (which should be a minimum of about 100 ns) is measured by repeating the electron-spin echo sequence, while the interval between the flash and the pulses is systematically incremented.

Electron-Spin Relaxation Rates

The values of T_1 and T_2 are measured in different experiments which observe the decay of the electron-spin echo with time; T_1 is measured with an inversion-recovery experiment as in NMR, while T_2 is observed by a two-pulse echo sequence, as in **Figure 8a**. The amplitude of the echo decreases with increasing delay time τ , owing to loss of 'phase memory'. The spin-spin relaxation is affected by various factors, including molecular motion and spin-spin interactions between paramagnets.

Hyperfine Couplings

Electron-spin echo envelope modulation (ESEEM) spectroscopy is a pulsed technique that detects weak hyperfine and quadrupolar couplings in the solid state. It is complementary to ENDOR in that it gives the best results in the intermediate regime of hyperfine couplings where $A \approx \nu_N$; in addition, it is particularly sensitive to couplings with quadrupolar nuclei such as ^2H and ^{14}N . The Mims three-pulse echo sequence is similar to the two-pulse sequence (**Figure 8b**) except that the π pulse is split into two $\pi/2$ pulses separated by time T . The decay of the echo is now determined by the slower spin–

Figure 8 Pulsed EPR experiments. (a) flash photolysis, (b)–(d) ESEEM.

lattice relaxation time T_1 allowing echoes to be detected over a longer period of time. During the evolution of the spin echo, hyperfine coupling frequencies cause dephasing of the electron spins, and so the echo amplitude is modulated with time (**Figure 8c**). This can be considered as being due to an interference between the frequencies of the allowed transitions, $\Delta m_S = \pm 1$, with the 'semi-forbidden' transitions, $\Delta m_S = \pm 1$, $\Delta m_I = \pm 1$, which are allowed owing to quadrupolar interactions and anisotropy of the hyperfine interaction. Fourier transformation of the time-domain spectrum yields the spectrum of hyperfine frequencies (**Figure 8d**).

Two-dimensional pulsed EPR experiments are also possible, such as HSCORE (hyperfine sublevel correlation) spectroscopy. This uses a pulse sequence as in **Figure 8b**, separated by an inversion pulse into two variable time intervals. Fourier transformation in the two time-domains gives a 2D spectrum, in which the effects of multiple hyperfine couplings can be resolved.

Pulsed ENDOR is an alternative technique, in which radiofrequency pulses at NMR frequencies are used to perturb the spin-echo sequence (**Figure 9**). Hyperfine interactions lead to loss of coherence of the electron spins during the mixing period, so the amplitude of the echo is decreased. A plot of echo amplitude against RF frequency yields a spectrum analogous to that of a CW ENDOR spectrometer.

Types of Material Studied

Free Radicals

Organic free radicals can be produced by one-electron oxidation or reduction reactions, by irradiation processes or by homolytic cleavage of a chemical bond. They may occur in the solid, liquid or gaseous states. Organic radicals in solution give complex EPR spectra. The hyperfine structure of their spectra provides information about

the type of radical and the distribution of the unpaired electron in it. Free radicals tend to be unstable and to decay by recombination processes. However, some radicals, particularly those in the solid state, are stable. If they have a half-life of at least a few seconds, they can readily be examined by conventional EPR spectroscopy, using rapid-scan coils to sweep the B_0 field. If they are more short-lived, the radical may be stabilized by cooling to low temperatures, or chemically trapped with a spin trap which reacts with the unstable species to produce a more stable radical.

Spin Traps

Ideally, a spin trap is a diamagnetic compound, which is introduced into a biological system without perturbing it and which reacts rapidly and specifically with a transient free radical to form a stable radical that can be identified from its EPR signal. These requirements are somewhat contradictory. The two most commonly used spin traps for organic radicals are nitroso compounds and nitrones (**Table 4**). These react with radicals to form nitroxides. The nitroso compounds give an adduct in which the radical added is bonded directly to the nitroxide nitrogen, so that the hyperfine splittings in the EPR signal are more diagnostic of the original radical; however, the adducts are less stable and may decay within minutes. Nitrones tend to give more stable adducts which are more difficult to identify.

Spin Labels

Spin labels are stable paramagnetic molecules that are introduced into a biological sample, and extend the use of EPR to situations where no endogenous radicals exist. The commonest type of spin labels are nitroxides (aminoxyl) radicals, though other types of radicals and transition metal ions have been used. The advantage of the

Figure 9 Principle of Mims pulsed ENDOR.

Table 4 Types of spin traps

Type of spin trap	Structure	Suitable application
2-Methyl-2-nitrosopropane (MNP)		C,S-centred radicals
5,5-Dimethyl-1-pyrroline- <i>N</i> -oxide (DMPO)		C,S,O-centred radicals
<i>N</i> - <i>tert</i> -Butyl- α -phenylnitron (PBN)		C,S,O-centred radicals
Fe ^{II} (diethyldithiocarbamate) ₂		Nitric oxide

specific labelling approach is that it makes it possible, through judicious labelling, to investigate the local environment and motion of defined parts of the system under study.

Transition Metals

Transition metals are paramagnetic in certain oxidation states (Table 2). Although this paramagnetism is stable, the sample may have to be cooled to low temperatures for the EPR signal to be observed.

Defects in Solids

Examples of defects are cation vacancies (V centres), anion vacancies (F centres) and impurities in crystals. Defects can be generated in various ways, such as irradiation with ultraviolet or ionizing radiation, or by imperfect crystallization. An example is a defect (latent image) generated in photographic emulsion by light irradiation. In addition, finely divided solid materials commonly show radical centres due to homolytic cleavage of chemical bonds.

Information from EPR Spectroscopy

Identification of the Paramagnet

The type of paramagnetic species may be recognized from the characteristic features of its spectrum such as g factors and hyperfine splittings.

For free radicals in solution, examination of the pattern of hyperfine splittings can provide information about the number of interacting nuclei and hence the structure

of the radical. For example, in the benzoquinone radical (Figure 3a), the splitting by four equivalent protons gives rise to five lines with amplitudes in the ratio 1:4:6:4:1.

A powerful technique is to substitute atoms in the molecule with nuclei having different nuclear spins, for example deuterium ^2H ($I = 1$) for ^1H or ^{13}C ($I = \frac{1}{2}$) for ^{12}C . Examples of nuclear spins and moments are given in Table 1. The observed change in the hyperfine splitting pattern is conclusive evidence of interaction with the nucleus.

Quantification

The concentration of unpaired electrons can be determined from the integrated intensity of the EPR spectrum by double integration or by numerical simulation of the spectrum. For paramagnets with spin $\frac{1}{2}$, measured under non-saturating conditions, the integrated intensity for a given concentration is the same, regardless of the nature of the paramagnetic species. Hence the concentration can be referred to a standard material such as Cu^{II} .

Spin Hamiltonian Parameters

The parameters of the EPR spectrum are described formally by a spin Hamiltonian equation, which summarizes the energies of the different types of interaction. For example, the Hamiltonian for a spin S interacting with a nuclear spin I is

$$\mathcal{H} = g\mu_{\text{B}}B_0S + AIS$$

where the operators g and A are shorthand notation for 3×3 matrices or tensors. The EPR spectrum may be

interpreted by computer simulation of the energy of interaction with the magnetic field B_0 . This provides information about the electronic state of the paramagnet. For radicals, the information can be used in detailed molecular orbital calculations of electronic structure. For transition metal ions, EPR provides information about the coordination geometry, spin state and types of ligands.

Redox and Spin States

Changes in oxidation states of paramagnets, by adding or removing unpaired electrons, cause the EPR signals to appear and disappear. This can be used to monitor oxidation–reduction reactions, and to measure reduction potentials. Generally the EPR spectrum is a useful indication of the oxidation–reduction state of the species observed. Often the presence of an EPR signal is conclusive, though in the case of semiquinones they may be anion radicals (formed by electron addition) or cation radicals (formed by removal of an electron). The EPR spectra of Ni^{I} and Ni^{III} are similar. In these cases further oxidation–reduction experiments are needed to distinguish them.

For transition ions such as Fe^{III} , the EPR spectrum is a good indicator of spin state, in this case high spin ($S = \frac{5}{2}$) or low spin ($S = \frac{1}{2}$). The spectra of the high-spin states are influenced by zero-field splittings, in this case giving g factors of up to 10.

Distances

The hyperfine coupling between an electron spin and a nucleus or between electron spins consists of two components: an exchange interaction (acting through chemical bonds, and generally isotropic), and a dipolar interaction. The dipolar component is anisotropic and its magnitude is inversely proportional to the (distance)³, and this can be used to estimate distances. In favourable cases, hyperfine couplings from ENDOR can be used to determine distances of protons up to 0.5 nm. Electron spin–spin interactions can be observed as splittings in the EPR spectrum over distances up to 1.5 nm, and relaxation effects at distances up to 4 nm.

Orientation

If the molecules of a paramagnet are orientated, as in a single crystal, the EPR signal consists of narrow lines, which shift as the crystal is rotated in the magnetic field. The angular dependence can be measured precisely using a goniometer. Some ordering is seen in fibres and layered materials, though less precisely than in crystals. From this orientation dependence it is possible to estimate the spin Hamiltonian parameters, yielding detailed

information about the axes of the g and A matrices, and hence the orbital states.

Motion

The line width of the EPR spectrum of a radical such as a nitroxide in solution is sensitive to motion in the range of correlation times 10^{-7} – 10^{-11} s. This is due to the anisotropy of the ^{14}N hyperfine splitting. If the motion is rapid enough to average this anisotropy, the spectrum shows narrow lines. For slower motion the spectrum broadens out. The rate of motion is determined by simulation, or by comparison with labelled molecules of known correlation time. By means of an experimental technique known as saturation-transfer EPR the spectra may be made to be sensitive to correlation times up to 10^{-3} s, as found, for example, in membrane-bound proteins.

EPR Dosimetry

The build-up of radicals in irradiated solids forms a method of estimating the absorbed dose of ionizing radiation. A standard used in EPR dosimeters is the amino acid alanine, in pellet form, which gives a linear relationship between radical signal amplitude and absorbed dose over several orders of magnitude. Where there has been accidental radiation exposure, the EPR of radicals in hydroxyapatite in tooth enamel has been used to estimate the absorbed dose. Irradiation of foods such as meat may be detected by radicals formed in bone.

EPR Dating

Buried archaeological samples that contain crystalline materials show radical EPR signals due to the effects of the radiation in the soil. The time of burial can be estimated by taking measurements of the radioactive isotopes in the surrounding soil and observing the signal amplitude after applying an equivalent dose of radiation to the sample. The decay of the radical signal over time depends on the stability of the defects in the material. Dating works best for crystalline material such as silica; bone is unreliable because of recrystallization. The technique has been used for samples dated between 10^5 and 10^6 years, which is between the ranges possible for radiocarbon and potassium dating.

Medical Applications

Oxygen radicals have been widely investigated in biomedical systems and are of great interest because of their cytotoxic effects and involvement in processes such as inflammation. They may be observed by spin traps (Table 4). Nitric oxide is also generated in conditions such as inflammation, and can be trapped by iron complexes such as iron diethyldithiocarbamate.

Oximetry exploits another feature of the spectra of radicals in solution: that they are broadened by paramagnetic interactions with oxygen in solution. With narrow-line radicals it is possible to measure oxygen in human tissues at concentrations below $10^{-5} \text{ mol dm}^{-3}$.

r	distance between the spins
$\mathbf{r}$	vector relating electron and nuclear moments
S	electron spin quantum number
S_z	vector of the electron spin quantum number in the z direction
T_{1e} and T_{2e}	spin–lattice and spin–spin relaxation times, respectively
α and β	refer to electron spin
μ	magnetic moment
μ_B	Bohr magneton
μ_N	nuclear magneton
ν	frequency

This article will discuss the concept and outline the theory of electron paramagnetic resonance (EPR), sometimes known as electron spin resonance (ESR), spectroscopy. Paramagnetism arises as a consequence of unpaired electrons present within an atom or molecule. It can be said that EPR is the most direct and sensitive

technique to investigate paramagnetic materials. It will not be possible within this article to fully expound on all the theoretical aspects of EPR and so the reader is encouraged to refer to the excellent texts listed in the Further Reading section.

Consequently this work is aimed at professional scientists who would like to expand their knowledge of spectroscopic techniques and also at undergraduates with the intention of allowing them to fully appreciate the scope, versatility and power of the technique.

Basic Principles of the EPR Experiment

The electron is a negatively charged particle that moves in an orbital around the nucleus and so consequently has orbital angular momentum. It also spins about its own axis and therefore has a spin angular momentum given by

$$\text{spin angular momentum} = \hbar/2\pi[S(S+1)]^{1/2} \quad [1]$$

where S is called the spin quantum number, with a value of $\frac{1}{2}$, and $\hbar$ = Planck's constant (6.626×10^{-34} Js). If we restrict ourselves to one specified direction, the z direction, then the component of the spin angular momentum can only assume two values and consequently $S_z = M_S \hbar/2\pi$. The term M_S can have $(2S+1)$ different values of $+S, (S-1), (S-2), \dots, (-S)$. If the possible values of M_S differ by one and range from $-S$ to $+S$ then the only two possible values for M_S are $\frac{1}{2}$ and $-\frac{1}{2}$.

Associated with the electron spin angular momentum is a magnetic moment μ and it is related to the spin as follows

$$\mu = g_e \hbar/4\pi m_e [S(S+1)]^{1/2} \quad [2]$$

where m_e = mass of electron, e = electron charge, S = spin quantum number and g_e is the spectroscopic factor known as the g factor (which has a value of 2.0023 for a free electron). The above equation can be rewritten as

$$\mu = -g_e \mu_B S/\hbar \quad [3]$$

where $\mu_B = eh/2m_e$ and $\hbar = h/2\pi$. The z axis component μ_z will then be

$$\mu_z = -g_e \mu_B M_S \quad [4]$$

μ_B is the Bohr magneton and has the value 9.2740×10^{-24} J T⁻¹. The negative sign arises because of the

negative charge on the electron which results in the magnetic dipole being in the opposite direction to the angular momentum vector. The electron is restricted to certain fixed angular positions that correspond to the z component of the spin angular momentum; S_z is a half integral number (M_S) of $\hbar/2\pi$, units. Since $S = \frac{1}{2}$ then $[S(S+1)]^{1/2}$ cannot be $\frac{1}{2}$ and consequently the spin angular momentum vector $\mathbf{s}$ and the magnetic moment vector $\boldsymbol{\mu}$ can never be aligned exactly in the field direction and they maintain a constant angle θ with the z axis and hence the applied field (Figure 1).

Hence, for a single unpaired electron, where $S = \frac{1}{2}$, the magnitude of the spin angular momentum along the z axis will be given by $+\hbar/2$ and $-\hbar/2$. For a free electron the spin angular momentum can have two possible orientations and these give rise to two magnetic moments or spin states of opposite polarity. In the absence of an external magnetic field the two spin states are degenerate. However, if an external magnetic field is applied then the degeneracy is lifted, resulting in two states of different energy. The energy of the interaction between the electron magnetic moment and the external magnetic field is given by

$$E = -\mu_z B \quad [5]$$

where B = the strength of external magnetic field and μ_z = magnetic dipole along the z axis. In quantum mechanics the μ vector is replaced by the corresponding operator leading to the following Hamiltonian

$$H = -g_e \mu_B B S_z \quad [6]$$

so that the energy is given by $E = -g_e \mu_B M_S B$. For a single unpaired electron $M_S = \pm \frac{1}{2}$ and this gives rise to two energy levels known as Zeeman levels. The difference between these two energy levels is known as the

Figure 1 Allowed values of the magnitude of the spin angular momentum along the z axis for $S = \frac{1}{2}$.

Zeeman splitting (see Figure 2):

$$E_1 = \frac{1}{2} g_e \mu_B B \quad M_S = +\frac{1}{2} \quad \alpha \text{ spin } \uparrow \quad [7]$$

$$E_2 = -\frac{1}{2} g_e \mu_B B \quad M_S = -\frac{1}{2} \quad \beta \text{ spin } \downarrow \quad [8]$$

Since $\Delta E \propto B$, the difference between the two energy levels is directly proportional to the external applied magnetic field. Transitions between the two Zeeman levels can be induced by the absorption of a photon of energy, $h\nu$, equal to the energy difference between the two levels:

$$\Delta E = g_e \mu_B B = h\nu \quad [9]$$

where h = Planck's constant and ν = frequency of electromagnetic radiation. The existence of two Zeeman levels, and the possibility of inducing transitions from the lower energy level to the higher energy level, is the very basis of EPR spectroscopy. We can see, therefore, that the position of absorption varies directly with the applied magnetic field. EPR spectrometers may operate at different fields and frequencies (two common frequencies being ~ 9.5 and ~ 35 GHz, known as X and Q band respectively). It is therefore far more convenient to refer to the absorption in terms of its g value:

$$g = \Delta E / \mu_B B = h\nu / \mu_B B \quad [10]$$

Figure 2 The Zeeman energy levels of an electron ($S = \frac{1}{2}$) in an applied magnetic field for a fixed microwave frequency.

Larmor Precession, Spin Populations and Relaxation Effects

It was noted above that the two spin states were at a constant angle to the z axis. However, in the presence of a magnetic field, the magnetic moment of the electron cannot align with the applied field and a turning couple is set up which results in a precession of the spin states around the z axis (**Figure 3**). This gives a physical mechanism by which spins can interact with electromagnetic radiation. When the magnetic component of the microwave radiation, which is orthogonal to the applied field, is at a frequency equal to that of the *Larmor precession* then the two are said to be in resonance, and energy can be transferred to the electron, inducing $\Delta M_S = \pm \frac{1}{2}$ transitions.

The incident radiation induces transitions not only from the lower to the higher energy states but can also induce emission with equal probability. Consequently the extent of absorption will be proportional to the population difference between the two states. At thermal equilibrium the relative *spin populations* of the two Zeeman levels is given by a Boltzmann equation:

$$N_U/N_L = e^{-\Delta E/kT} \quad [11]$$

where k = Boltzmann constant, T = absolute temperature (K), N_L = number of electrons in the lower level, N_U = number of electrons in the higher level and ΔE = difference in energy between the two energy levels. At room temperature (300 K) and in a magnetic field of 300 mT the populations of the two Zeeman levels are almost equal, but a slight excess exists in the lower level and it is this that gives rise to a net absorption. However, this would very quickly lead to the disappearance of the EPR signal as the absorption of energy would equalize these two states. For the experiment to proceed there has to be a process by which energy is lost from the system. Such processes are known as *relaxation processes*.

Figure 3 Two allowed electron spin orientations and the corresponding Larmor precession for $S = \frac{1}{2}$.

To maintain a population excess, electrons in the upper level must be able to return to their low energy state. Therefore they must be able to transfer their excess spin energy either to other species or to the surrounding lattice as thermal energy. The time taken for the spin system to lose $1/e$ of its excess energy is called the relaxation time. Two such relaxation processes are:

- spin-lattice relaxation (T_{1e}): this process is due to lattice motions such as molecular tumblings in solids, liquids and gases which have a frequency comparable to that of the Larmor precession and this provides a pathway which allows the electron's excess energy to be transferred to the surroundings.
- spin-spin relaxation (T_{2e}): the excess spin energy is transferred between paramagnetic centres through either dipolar or exchange coupling, from one molecule to another. This mode of relaxation is important when the concentration of paramagnetic species is high (spins are close together). If the relaxation time is too fast then the electrons will only remain in the upper state for a very short period of time and give rise to a broadening of the spectral line width as a consequence of Heisenberg's uncertainty principle.

In general $T_{1e} > T_{2e}$ and the line width depends only on the spin-spin interactions (T_{2e}). However, if, in certain circumstances, both spin-spin and spin-lattice relaxations contribute to the EPR line width (ΔH), then the resonance line width can be simply written as

$$\Delta H \propto 1/T_{1e} + 1/T_{2e} \quad [12]$$

When T_{1e} becomes very short, below $\sim 10^{-7}$ s, its effects on the lifetime of the species in a given energy level makes an important contribution to the line width. In some cases the EPR lines are broadened beyond detection. The term T_{1e} may also be inversely proportional to the absolute temperature ($T_{1e} \propto T^{-n}$) with n depending on the precise relaxation mechanism. In such cases, cooling the sample increases T_{1e} and usually leads to detectable lines. For this reason, EPR experiments are frequently recorded at liquid nitrogen (77 K) or helium (4 K) temperatures.

Basic Interaction of the Electron with Its Environment

An expression for the spin state energies of an electron whose only interaction was with an applied magnetic field (a free electron) was derived above (eqn [6]). This represents an idealized model as in the real situation the electron suffers a variety of electrostatic and magnetic interactions which complicate the resonances. Consequently we must be able to account for these deviations. Magnetic resonance spectroscopists seek to

characterize and interpret EPR spectra and these deviations quantitatively using a device known as a *spin Hamiltonian*. The EPR spectrum is essentially interpreted as the allowed transitions between the eigenvalues of this spin Hamiltonian. The Hamiltonian contains terms which reflect the interactions of the spins of electrons and nuclei with the applied magnetic field and with each other, e.g.

$$H = \mu_B \mathbf{B} g \mathbf{S} + \sum_j \mathbf{I} A \mathbf{S} + \sum_j g_N \mu_N \mathbf{B} \mathbf{I} \quad [13]$$

Analysis of a spectrum amounts to identifying which interactions are involved. The origin of the various terms in this spin Hamiltonian will be examined below. For example, changes in the g factor are shown for a variety of paramagnetic species in Table 1.

The g Tensor: Significance and Origin

The main reason for the deviation in g values comes from a spin-orbit coupling that results in an orbital contribution to the magnetic moment. This arises from the effect of the orbital angular momentum L which is non-zero in the case of orbitals exhibiting p, d or f character. In this case the spin is no longer exactly quantized along the direction of the external field and the g value cannot be expressed by a scalar quantity but becomes a tensor. The orbital angular momentum L is associated with a magnetic momentum given by

$$\mu_L = \mu_B L \quad [14]$$

For a system with a doublet ($S = \frac{1}{2}$) non-degenerate electronic ground state, the interaction with the external magnetic field can be expressed in terms of a perturbation of the general Hamiltonian by the following three terms

$$H = g_e \mu_B \mathbf{B} \mathbf{S} + \mu_B \mathbf{B} \mathbf{L} + \lambda \mathbf{L} \mathbf{S} \quad [15]$$

Table 1 Isotropic g value variations for a series $S = \frac{1}{2}$ paramagnetic species. For organic radicals the g value deviations (from g_e) are usually small, less than 1%, but for systems that contain heavier atoms, such as transition metal ions, the variations can be much larger

Species	g value
e^-	2.0023
$\text{CH}_3^\bullet$	2.0026
Anthracene radical cation	2.0028
Anthracene radical anion	2.0029
1,4-Benzoquinone radical anion	2.0047
SO_2^-	2.0056
$\text{HO}_2^\bullet$	2.014
$\{(\text{CH}_3)_3\text{C}\}_2\text{NO}$	2.0063
Copper(acetonil acetate)	2.13
VO(acetonil acetate)	1.968
Cyclopentadienyl $\text{TiCl}_2\text{AlCl}_2$	1.975

The first and second terms correspond, respectively, to the electron Zeeman and orbital Zeeman energies. The third one represents the energy of the spin-orbit coupling where λ is the spin-orbit coupling constant which mixes the ground state wavefunctions with the excited states. The extent of the interaction between L and S mainly depends on the nature of the system considered and in many instances this interaction is stronger than that between the magnetic field and the orbital angular momentum. Depending on the strength of the molecular electric field, two limiting cases can be distinguished:

- Strong fields: L must align itself along the field so that only S can orient itself with respect to the external magnetic field and contribute to the paramagnetism. In this case $g = g_e$. Many organic radicals or systems in which the unpaired electron is in a molecular orbital delocalized over a large molecule experience this situation.
- Weak fields: L is no longer under the constraint of this weak field and the spin-orbit coupling $L + S$ can take place, giving a resultant total angular momentum:

$$\mathbf{J} = \mathbf{L} + \mathbf{S} \quad [16]$$

associated with the magnetic moment:

$$\mu_J = -g_J \mu_B \mathbf{J} \quad [17]$$

where g_J is called the Landé g factor. This situation occurs in the rare earth elements.

When intermediate fields are present in the paramagnetic centre, L is only partially blocked by the molecular field (transition metal ions, inorganic radicals). The system must be treated in terms of the perturbation Hamiltonian in eqn [6] which can be written as

$$H = \mu_B \mathbf{B} g \mathbf{S} \quad [18]$$

The g_e scalar value reported in eqn [6] is now replaced by g , a second rank tensor which represents the anisotropy of the interaction between the unpaired electron and the external magnetic field and also outlines the fact that the orbital contribution to the electronic magnetic momentum may be different along different molecular axes.

The g tensor may be depicted as an ellipsoid whose characteristic (principal) values (g_{xx} , g_{yy} , g_{zz}) depend upon the orientation of the symmetry axes of the paramagnetic entity with respect to the applied magnetic field (Figure 4). The most general consequence of the anisotropy of g from an experimental point of view, is therefore that the resonance field of a paramagnetic species, for a given frequency, depends on the orientation of the paramagnetic centre in the field itself. The g value for a given orientation depends on ϕ and θ values

Figure 4 Orientation of the magnetic field $\mathbf{B}$ with respect to the $\mathbf{g}$ tensor ellipsoid in the crystallographic frame x, y, z . The characteristic angles θ and ϕ define the orientation of $\mathbf{B}$ which leads to the $\mathbf{g}(\theta, \phi)$.

according to J; the relation $g^2 = g_{xx}^2 \cos^2 \phi \sin^2 \theta + g_{yy}^2 \sin^2 \phi \cos^2 \theta + g_{zz}^2 \cos^2 \theta$. Accordingly, the Zeeman resonance will occur at field values given by

$$B_{\text{res}} = h\nu / \mu_B (g_{xx}^2 \cos^2 \phi \sin^2 \theta + g_{yy}^2 \sin^2 \phi \cos^2 \theta + g_{zz}^2 \cos^2 \theta)^{-1/2} \quad [19]$$

In the most general case, the resonance observed for a paramagnetic centre in a single crystal is obtained at distinct field values of B_x , B_y and B_z when the magnetic field is parallel to the x , y or z crystal axis respectively. The g values corresponding to these three orientations (g_{xx} , g_{yy} and g_{zz}) are the principal (diagonal) elements of the g tensor. When the principal axes of the crystal are not known, the g tensors can be labelled g_1 , g_2 and g_3 . Absolute determination of the g values may in principle be carried out by independent and simultaneous measurement of B and ν using a gaussmeter and a frequency meter, respectively, following the equation

$$g = h\nu / \mu_B B \quad [20]$$

The A Tensor: Significance and Origin

The source of this splitting is the magnetic interaction between the electron spin and neighbouring nuclear spins, which gives rise to hyperfine structure in the spectra. It arises because a nearby magnetic nucleus gives rise to a local field, $\mathbf{B}_{\text{local}}$, which must be compounded

with the applied magnetic field $\mathbf{B}$ to satisfy the EPR condition $h\nu = g_e \mu_B \mathbf{B}$. We must now rewrite this equation as

$$h\nu = g_e \mu_B (\mathbf{B} + \mathbf{B}_{\text{local}}) \quad [21]$$

and clearly the value of $\mathbf{B}$ required to achieve resonance will depend on $\mathbf{B}_{\text{local}}$ (i.e. the magnetic moments of the nuclei). Several nuclei possess spin and corresponding magnetic moments. The nuclear spin quantum number (I) of a given nucleus can assume integral or half-integral values in the range 0–6. The magnetic moment μ_n associated to a nucleus is collinear with the spin vector I according to the relation

$$\mu_n = g_n \mu_N I \quad [22]$$

which is similar to eqn [4]; g_n is the nuclear g factor and μ_N the nuclear magneton which is smaller than the Bohr magneton by a factor of 1838, i.e. the ratio of the mass of a proton to that of an electron.

When the paramagnetic centre contains one or more nuclei with non-zero nuclear spin ($I \neq 0$), the interaction between the unpaired electron and the nucleus with $I \neq 0$ produces further splittings of the Zeeman energies and consequently there are new transitions, which are responsible for the so-called hyperfine structure of the EPR spectrum.

Let us consider the proton as a case in point; it is a spinning positive charge and has its own associated magnetic field and consequently can interact with both the external magnetic field (cf. NMR) and that of the electron, i.e. it has a nuclear spin $I = \frac{1}{2}$ and $M_I = \pm \frac{1}{2}$. This leads to a situation whereby the energy of the system can either be lowered or be raised depending on whether the two spins are parallel or antiparallel. The energy of an electron with spin quantum number M_S and a nucleus with spin quantum number M_I is given by

$$E(M_I, M_S) = g_e \mu_B B M_S - g_N \mu_N B M_I + h A_0 M_S M_I \quad [23]$$

where A_0 is the isotropic coupling constant. The first term in the equation gives the contribution due to the interaction of an electron with an applied field, giving rise to two electron Zeeman levels. The second term is the contribution due to the interaction of the nucleus with the applied magnetic field, the nuclear Zeeman levels (Figure 5). The final term is the energy of interaction between the unpaired electron and the magnetic nucleus. If we now substitute the values for M_S and M_I then the interaction, between an unpaired electron ($S = \frac{1}{2}$) and a single proton ($I = \frac{1}{2}$), gives rise to four energy levels, E_1 to E_4 . These are calculated to be

$$E_1 = \frac{1}{2} g_e \mu_B B - \frac{1}{2} g_N \mu_N B + \frac{1}{4} h A_0 \quad \begin{matrix} M_S \\ +\frac{1}{2} \end{matrix} \quad \begin{matrix} M_I \\ +\frac{1}{2} \end{matrix} \quad [24]$$

Figure 5 Energy level manifold in a high magnetic field, resulting from the interaction of an unpaired electron ($S = \frac{1}{2}$) with a nucleus of $I = \frac{1}{2}$. Note that $a > 0$. $|a/2| < V_n$.

$$E_2 = \frac{1}{2}g_e\mu_B B + \frac{1}{2}g_N\mu_N B - \frac{1}{4}bA_0 \quad +\frac{1}{2} - \frac{1}{2} \quad [25]$$

$$E_3 = -\frac{1}{2}g_e\mu_B B + \frac{1}{2}g_N\mu_N B + \frac{1}{4}bA_0 \quad -\frac{1}{2} - \frac{1}{2} \quad [26]$$

$$E_4 = -\frac{1}{2}g_e\mu_B B - \frac{1}{2}g_N\mu_N B - \frac{1}{4}bA_0 \quad -\frac{1}{2} + \frac{1}{2} \quad [27]$$

The selection rules for the allowed transitions between the energy levels are

$$\Delta M_I = 0 \quad \text{and} \quad \Delta M_S = \pm 1 \quad [28]$$

Thus two resonance transitions can occur at

$$\Delta E_A = E_1 - E_4 = g_e\mu_B B + \frac{1}{2}bA_0 \quad [29]$$

$$\Delta E_B = E_2 - E_3 = g_e\mu_B B + \frac{1}{2}bA_0 \quad [30]$$

These two possible transitions give rise to two absorption peaks which, at constant applied microwave frequency, occur at magnetic fields of values

$$B_1 = \frac{b\nu}{g_e\mu_B} - \frac{bA_0}{2g_e\mu_B} = \frac{b\nu}{g_e\mu_B} - \frac{a}{2} \quad [31]$$

$$B_2 = \frac{b\nu}{g_e\mu_B} + \frac{bA_0}{2g_e\mu_B} = \frac{b\nu}{g_e\mu_B} + \frac{a}{2} \quad [32]$$

where $a = bA_0/g_e\mu_B$ and is the hyperfine coupling constant (HFCC) given in mT. The spectrum obtained for such a system would be a doublet centred at the g value and separated by the hyperfine coupling constant (hfc) a . If we extend the number of equivalent nuclei then the complexity of the spectrum increases in a manner described in Table 2. A further example is given in Figure 6 for the radical anion of naphthalene.

It is now necessary to examine the mechanisms by which the hyperfine interactions arise. Two types of electron-spin–nuclear-spin interactions must be considered, of isotropic and anisotropic nature.

The Isotropic Interaction

This concerns exclusively s-type orbitals or orbitals with partial s character (such as hybrid orbitals constructed from s-type orbitals) because only these orbitals have a finite probability density at the nucleus. This mechanism is a quantum interaction related to the finite probability of the unpaired electron at the nucleus and is termed the Fermi contact interaction. The corresponding isotropic coupling constant a_{iso} is given by

$$a_{\text{iso}} = (8\pi/3g_e g_N \mu_B \mu_N) |\psi(0)|^2 \quad [33]$$

Table 2 Line intensities for a series of nuclei with different values of I . For the case of $I = \frac{1}{2}$ the line intensities can be described by the expansion of $(x+1)^2$ and hence follow Pascal's triangle

Nuclei	Intensity of lines
$I = \frac{1}{2}$, e.g. ^1H	
Number of equivalent nuclei	
1	1 1
2	1 2 1
3	1 3 3 1
4	1 4 6 4 1
$I = 1$, e.g. ^{14}N	
Number of equivalent nuclei	
1	1 1 1
2	1 2 3 2 1
3	1 3 6 7 3 1
4	1 4 10 16 19 16 10 4 1
$I = \frac{3}{2}$, e.g. $^{63,65}\text{Cu}$	
Number of equivalent nuclei	
1	1 1 1 1
2	1 2 3 4 3 2 1

Figure 6 EPR spectrum of the radical anion of naphthalene in tetrahydrofuran as solvent. The radical was formed by dissolving naphthalene in sodium-dried tetrahydrofuran under vacuum and passing the resultant solution over a sodium metal film, again under vacuum conditions. The number of lines is given by $2nI + 1$ where I equals the nuclear spin and n the number of nuclei. HFCC for 1,4,5,8 = 0.483 mT and for 2,3,6,7 = 0.185 mT.

where g_n and μ_N are the nuclear analogues of g_e and μ_B , respectively, and $|\psi(0)|^2$ is the square of the absolute value of the wavefunction of the unpaired electron evaluated at the nucleus.

Since s orbitals have a high electron density at the nucleus, the hyperfine coupling constant will be large and since s orbitals are also symmetrical it will be

independent of direction. The spherical symmetry of s orbitals accounts for the isotropic nature of the contact interaction.

Thus in the case of the hydrogen atom ($M_I = \frac{1}{2}$) with 100% spin density in the $1s$ orbital, the EPR spectrum is composed of two resonance lines separated by approximately 50.8 mT. In the case of naphthalene, the smaller spin density associated with the ^1H s orbital results in a smaller isotropic coupling.

The Anisotropic Interaction

In non-spherically symmetric orbitals (p , d or f) there is no electron density at the nucleus and the electron is to be found some distance away. The interaction between it and the nucleus will be as two magnetic dipoles and consequently the interaction will be small and dependent on the direction of the orbital with respect to the applied magnetic field as well as to their separation. The coupling then arises from the classical dipolar interaction between magnetic momenta whose energy is given by

$$E = \mu_s \mu_n / r^3 - 3(\mu_s \mathbf{r})(\mu_n \mathbf{r}) / r^5 \quad [34]$$

where $\mathbf{r}$ is the vector relating the electron and nuclear moments and r is the distance between the two spins. The above equation gives the energy of interaction of two bar magnets if their size is small compared with the distance between them. Moving to quantum mechanics we construct the Hamiltonian by replacing the magnetic moments by the appropriate operators. The quantum mechanics analogue of eqn [34] is then obtained by replacing μ_s and μ_n by their expressions given in eqns [4] and [22]:

$$H_{\text{aniso}} = -g_e \mu_B g_n \mu_N (\mathbf{I} \cdot \mathbf{S} / r^3 - 3(\mathbf{I} \cdot \mathbf{r})(\mathbf{S} \cdot \mathbf{r}) / r^5) \quad [35]$$

Equation [35] must be averaged over the entire probability of the spin distribution. H_{aniso} is averaged out to zero when the electron cloud is spherical (s orbital) and comes to a finite value in the case of axially symmetric orbitals (p orbitals, for instance). In addition, in the case of very rapid tumbling of the paramagnetic species (as occurs in a low viscosity solution) the anisotropic term of the hyperfine interaction is averaged to zero and the isotropic term is the only one observed.

Combination of Isotropy and Anisotropy

Since any orbital may be considered as a hybrid of suitable combinations of s , p or d orbitals, so also may a hyperfine coupling be divided into a contribution arising from p or d orbitals (anisotropic) and s orbitals (isotropic). In general both isotropic and anisotropic hyperfine couplings occur when one or more nuclei with $I \neq 0$ are present in the system. The whole interaction is therefore dependent on orientation and must be expressed by the second rank A tensor as given in eqn [13]. The A tensor may be split into

anisotropic and isotropic parts as follows

$$A = \begin{vmatrix} A_1 & 0 & 0 \\ 0 & A_2 & 0 \\ 0 & 0 & A_3 \end{vmatrix} = a_{\text{iso}} + \begin{vmatrix} T_1 & 0 & 0 \\ 0 & T_2 & 0 \\ 0 & 0 & T_3 \end{vmatrix} \quad [36]$$

with $a_{\text{iso}} = (A_1 + A_2 + A_3)/3$. In a number of cases, the second term of eqn [36] is a traceless tensor ($T_1 + T_2 + T_3 = 0$) and has the form $(-T, -T, 2T)$. The anisotropic part of the A tensor corresponds to the dipolar interaction as expressed by the Hamiltonian in eqn [13]. The s and p character of the orbital hosting the unpaired electrons are given by the following relations:

$$c_s^2 = a_{\text{iso}}/a_0 \quad \text{and} \quad c_p^2 = b/b_0 \quad [37]$$

where a_0 and b_0 are the theoretical hyperfine coupling constants (assuming pure s and p orbitals for the elements under consideration). The terms a_{iso} and b are the experimental isotropic and anisotropic coupling constants respectively.

The D Tensor: Significance and Origin

The spin Hamiltonian described in eqn [13] applies to the case where a single electron ($S = \frac{1}{2}$) interacts with the applied magnetic field and with surrounding nuclei. However, if two or more electrons are present in the system ($S > \frac{1}{2}$), a new term must be added to the spin Hamiltonian (eqn [13]) to account for the interaction between the electrons. At small distances, two unpaired electrons will experience a strong dipole–dipole interaction, analogous to the interaction between electron and magnetic dipoles, which gives rise to anisotropic hyperfine interactions. The electron–electron interaction is described by the spin–spin Hamiltonian given in eqn [38]:

$$H_{ss} = SDS \quad [38]$$

where D is a second rank tensor (the zero-field parameter) with a trace of zero. As with the g and A tensors, the D tensor can also be diagonalized so that $D_{xx} + D_{yy} + D_{zz} = 0$. Equation [38] can be added to eqn [18] to obtain the correct spin Hamiltonian for an $S > \frac{1}{2}$ system (in the absence of any interacting nucleus):

$$H = \mu_B B g S + SDS \quad [39]$$

Since the trace of D is zero, calculation of the energy state for a system with $S=1$ requires only two independent parameters which are designated D and E . The spin coupling is direct in the case of organic

molecules in the triplet state and biradicals, but occurs through the orbital angular momentum in the case of transition metal ions. In the latter case, the D and E terms depend on the symmetry of the crystal field acting on the ions:

$$H = D \left(S_z^2 - \frac{S^2}{3} \right) + E(S_x^2 - S_y^2) \quad [40]$$

For axially symmetric molecules, the calculated shape of the $\Delta M_S = 1$ lines are given in **Figure 7a**. The separation of the outer lines is $2D'$ (where $D' = D/g\mu_B$) while that of the inner lines is D (E is zero in this case). The theoretical line shape for a randomly oriented triplet system with $E \neq 0$ is shown in **Figure 7b**. The separation of the outermost lines is again $2D'$ whereas that of the intermediate and inner pairs is $D' + 3E'/2$ and $D' - 3E'/2$ respectively. As the zero-field interactions become comparable to, and larger than, the microwave energy, the line shape exhibits severe distortions from the simulated case in **Figure 7**. Well-known examples of $S=1$ include the excited triplet state of naphthalene with $D/bc = 0.1003 \text{ cm}^{-1}$, $E/bc = -0.0137 \text{ cm}^{-1}$ and $g = 2.0030$.

Figure 7 Theoretical absorption and first derivative spectra of the $\Delta M_S = 1$ region of a randomly oriented triplet. (a) $S=1$ for a given value of D ($E=0$) and isotropic g . (b) $S=1$ where D is 6.5 times larger than E and g is isotropic.

Line Shapes and Symmetry Considerations in EPR Spectra

An important consideration in EPR is the effect of symmetry on the line shapes. In many cases the samples investigated by EPR are polycrystalline materials, composed of numerous small crystallites that are randomly oriented in space. The resultant *powder* EPR spectrum is the envelope of spectra corresponding to all possible orientations of the paramagnetic species with respect to the magnetic field; provided the resolution is adequate, the magnitude of the g and A tensor components can be extracted from

Figure 8 Powder EPR spectrum of a paramagnetic species with $I=0$ in axial symmetry. (a) absorption profile, (b) first derivative profile. The dotted lines have been calculated by assuming a zero line width whereas the solid lines correspond to a finite line width.

the powder spectra whereas no information can be obtained on the orientation of the tensor principal axes.

The profile of the powder spectrum is determined by several parameters, including the symmetry of the g tensor, the actual values of its components, and the line shape and the line width of the resonance. Concerning the symmetry of the g tensor, three possible cases can be identified.

Isotropy of g

In this case, the g tensor is characterized by $g_{xx} = g_{yy} = g_{zz} = g_{iso}$ and a single symmetrical line is observed. This simple situation is not very often encountered in powders except for some solid state defects and transition metal ions in highly symmetric environments such as O_h or T_d .

Axial Symmetry of g

Paramagnetic species isolated in single crystals exhibit resonances at typical magnetic fields which depend on

Figure 9 Effects of nuclear spin on the calculated powder EPR spectra for axial symmetry. The value of I varies from 0 to $\frac{3}{2}$. Note that the g values remain constant (illustrated by dotted lines). $g_{||}$ is split by $A_{||}$ and $g_{\perp}$ is split by $A_{\perp}$. The $A_{||}$ and $A_{\perp}$ values remain constant.

Figure 10 Powder EPR spectrum of a paramagnetic species in orthorhombic symmetry. (a) Absorption profile, (b) first derivative profile. The dotted and solid lines have the same significance as described in **Figure 7**.

their orientation and are given by eqn [19]. In the particular case of axial symmetry of the system, e.g. (C_{4n} , D_{4h}), if z is the principal symmetry axis of the species and θ the angle between z and the magnetic field, the x and y directions are equivalent and the angle ϕ becomes meaningless (**Figure 4**). Equation [19] reduces to

$$B_{\text{res}} = h\nu/\mu_B(g_{\perp}^2 \sin^2 \theta + g_{\parallel}^2 \cos^2 \theta)^{-1/2} \quad [41]$$

where $g_{\parallel} = g_{zz}$ and $g_{\perp} = g_{yy} = g_{xx}$ are the g values measured when the axis of the paramagnetic species is, respectively, parallel and perpendicular to the applied magnetic field.

Figure 11 Effects of nuclear spin on the calculated powder EPR spectrum of a species with orthorhombic symmetry. The spectrum is anisotropic both in g and A (g_1 is split by A_1 , g_2 is split by A_2 and g_3 by A_3). The value of I varies from 0 to $\frac{3}{2}$. It should be noted that when I assumes an integer value (as in c), the features of the original $I=0$ spectrum (a) are maintained in the centre of the spectrum. When I has half-integer values the hyperfine values are symmetrically disposed about the centre.

The powder spectrum is the envelope of the individual lines corresponding to all possible orientations in the whole range of ϕ . Assuming the microcrystals are randomly distributed, simple considerations show, however, that the absorption intensity, which is proportional to the number of microcrystals at resonance for a given θ value, is at a maximum when $\theta = \pi/2$ ($B_{\perp}$) and a minimum for $\theta = 0$ ($B_{\parallel}$); this allows the extraction of the $g_{\parallel}$ and $g_{\perp}$ values, which correspond to the turning points of the spectrum. **Figure 8** gives a schematic representation of the absorption curve and of its first derivative for a polycrystalline sample containing a paramagnetic centre with axial symmetry. The variation in the spectral profile for the same species as M_I varies is also shown in **Figure 9**.

Orthorhombic Symmetry of g

Three distinct principal components are expected in the case of a system with orthorhombic symmetry, e.g. (D_{2h} , C_{2v}). For polycrystalline samples, the absorption curve and its first derivative exhibit three singular points, corresponding to g_1 , g_2 and g_3 (Figure 10). For powder spectra the assignments of g_1 , g_2 and g_3 to the components g_{xx} , g_{yy} and g_{zz} related to the molecular axes of the paramagnetic centre is not straightforward and must be based on theoretical grounds or deduced from measurements of the same paramagnetic species in a single crystal. The situation becomes much more complicated in the presence of nuclei with $I \neq 0$. In several cases an initial interpretation of the experimental data can be achieved by using a simple analysis for the g tensor and neglecting second-order effects since the A tensor has the same type of angular dependence as the g tensor. Provided the principal axes are the same, then each of the three possible lines of the g tensor (g_1 , g_2 and g_3) will be split into a number of lines that depend on the nuclear spin with the spacing corresponding to the appropriate component of the A tensor (A_1 , A_2 or A_3); g_1 is split by A_1 , g_2 is split by A_2 and g_3 is split by A_3 (Figure 11).

Summary

The basic principles of EPR spectroscopy have been outlined. Although far from being an exhaustive treatment of the subject, it provides the reader with

essential knowledge of the technique and is a useful stepping stone for the articles on methods and instrumentation and applications.

ϵ	molar absorptivity
λ	wavelength
μ	electric transition moment
σ	wavenumber
Ψ_0	ground-state wavefunction

Circular dichroism spectroscopy (CD) is a powerful method for determining the absolute configurations and conformations of chiral molecules. In particular, the exciton-coupled circular dichroism arising from through-space chromophore – chromophore interactions, called exciton coupling, is one of the most sensitive spectroscopic tools for determining the molecular chirality of molecules in solution. The theoretical analysis of the exciton coupling phenomena is based on the coupled oscillator theory and molecular exciton theory. Since exciton-coupled CD is basically a nonempirical method, the derived conclusions are nonambiguous. It is a microscale technique of great versatility applicable to compounds ranging from small molecules to various types of ligand–receptor complexes. However, the extent of its potential has yet to be fully explored. Here the theory and applications of exciton-coupled CD are outlined.

When two chromophores with an identical or similar excitation energy are in close spatial proximity to one another and chirally disposed, the individuality of a monomer chromophore transition is lost. The chromophore

excited state can delocalize over all chromophores within the system and becomes an exciton. The excitons interact and couple, thus giving rise to a characteristic pair of intense CD bands with opposite signs and comparable band areas, called a CD exciton couplet. The coupling of two identical chromophores is illustrated in **Figure 1** by a steroidal 2,3-bis-*para*-substituted benzoate. The intense intramolecular charge-transfer (CT) bands stemming from the 1L_a transition of *para*-substituted benzoates give rise to the main electronic absorption band; it is the through-space coupling between these CT bands which is used for determining the absolute configuration between two hydroxyl groups. Although there is some free rotation around the C–O bonds, ester bonds are known to adopt the *s-trans* confirmation. Furthermore, X-ray crystallographic data, energy calculations, etc., show that the ester C=O is *syn* with respect to the methine hydrogens. Thus, the intramolecular CT transition polarized along the long axis of the benzoate chromophore is almost parallel to the alcoholic C–O bond. Hence the exciton CD data which represent the absolute chirality between the transition moments also represent the chirality between any two hydroxyl groups, provided that their spatial distance permits the two chromophores to couple. When the absolute sense of chirality between the C(2)–O and C(3)–O bonds constitute a clockwise twist as shown by the Newman projection in **Figure 1**, it is defined as positive, and vice versa.

The outline of exciton-coupled CD in a system consisting of two identical chromophores (a degenerate case) is as follows:

- Chromophores exhibit intense π – π^* absorptions.
- The excited state of the system is split into two energy levels, α and β , by exciton interaction between the two chromophores, and the energy gap $2V_{ij}$ is called the Davydov splitting.
- In the UV-visible spectra, this coupling gives rise to two-component spectra of the same sign which usually appears as a single absorption maximum with double intensity. In contrast, in CD, this excitation to two split energy levels gives rise to two CEs of opposite signs; summation of the two curves of opposite

Figure 1 Exciton coupling of two identical chromophores of steroidal 2,3-bisbenzoate with positive chirality; the carbinyl hydrogens are represented *syn* to the ester carbonyl and the ester groups is in an *s-trans* conformation. Also shown are the splitting of the excited states of isolated chromophores *i* and *j* into α and β states with the Davydov splitting $2V_{ij}$, summation of CD and UV curves (solid line) of two component curves (dotted line).

Table 1 Definition of exciton chirality for a binary system

	Qualitative definition	Quantitative definition	Cotton effects
Positive exciton chirality		$R_{ij} \cdot (\mu_{ioa} \times \mu_{j oa}) V_{ij} > 0$	Positive first and negative second Cotton effects
Negative exciton chirality		$R_{ij} \cdot (\mu_{ioa} \times \mu_{j oa}) V_{ij} < 0$	Negative first and positive second Cotton effects

signs separated by energy gap $\Delta\lambda$ results in a CD with two extrema, a couplet (commonly called a 'split CD'). The extrema at longer and shorter wavelengths are called the first CE (Cotton effect) and second CE, respectively.

- iv. The amplitude of exciton split CE is defined as the A value ($A = \Delta\epsilon_1 - \Delta\epsilon_2$), where $\Delta\epsilon_1$ and $\Delta\epsilon_2$ are intensities of the first and second CEs respectively.
- v. If the electric transition moments μ of the two chromophores constitute a right-handed screw, a positive couplet with positive first and negative second CEs are observed, and vice versa (Table 1).

- vi. The sign and intensity of exciton split CEs are governed by 'exciton chirality', which is theoretically defined as

$$R_{ij} \cdot (\mu_{ioa} \times \mu_{j oa}) V_{ij}$$

where R_{ij} is the interchromophoric distance vector from *i* to *j*, μ_{ioa} and $\mu_{j oa}$ are electric transition dipole moments of excitation $o \rightarrow a$ of groups *i* and *j*, respectively, and V_{ij} is interaction energy between two groups *i* and *j*.

- vii. The absolute configuration of two chromophores can be determined, provided that the direction of the transition moment in the chromophore is established.

Figure 2 (a) UV spectrum of anthracene in EtOH and polarization of the UV transitions. (b) CD and UV spectra of (6*R*,15*R*)-(+) -6,15-dihydro-6,15-ethanonaphtho[2,3-*c*]pentaphene [A] in 0.18% dioxane–EtOH. Adapted from Harada N et al. *Journal of the American Chemical Society* 98: 5408.

The cage compound [A] with two anthracene moieties, (6*R*,15*R*)-(+) -6,15-dihydro-6,15-ethanonaphtho[2,3-*c*]pentaphene (**Figure 2b**), provides a typical example of exciton-coupled CD. Of the four absorption bands of anthracene in the UV-visible region, the band at 252 nm ($\epsilon = 204\,000$, 1B_b transition) is the most intense and is polarized along the long axis of the chromophore. The UV of cage molecule [A] (**Figure 2b**) resembles that of anthracene (**Figure 2a**) with the expected bathochromic shift ($\lambda_{\max}$ 267.2 nm, $\epsilon = 268\,600$). The CD of (+)-[A] shows two intense CEs of opposite signs at the 1B_b transition: a first positive CE, $\lambda_{\text{ext}} = 268.0$ nm, $\Delta\epsilon = +931.3$, and a second negative CE, $\lambda_{\text{ext}} = 249.7$ nm, $\Delta\epsilon = -720.8$; $A = +1652.1$ (these CEs are one of the strongest ever observed!). The positive A value indicates that the two 1B_b transition moments along the long axes of the anthracene moieties constitute a clockwise screwsense. This leads to the 6*R*, 15*R* absolute configuration shown for (+)-[A].

Both exciton-coupled CD and X-ray techniques are nonempirical methods for determining the absolute configuration of chiral compounds. Although these two methods differ in that CD is for solutions whereas X-ray is for crystals, both methods naturally give the same absolute configuration.

The application of CD exciton coupling formalism to structural analysis started as the ‘dibenzoate chirality rule’, which became the ‘exciton chirality method’ when it was expanded to include the coupling between a variety of chromophores for determining the absolute configurations and/or conformations. As shown schematically in **Figure 1**, ‘exciton coupling’ is also present in UV-visible spectra, except that the electronic spectrum simply appears as a single maximum with double intensity; only in rare cases when the energy gap $2V_{ij}$ between the α and β levels is substantial will the spectra exhibit double maxima. **Figure 3a** (plotted in cm^{-1}) shows the broad UV-visible band with $\lambda_{\max} \approx 390$ nm of Schiff base [A]; upon protonation this is converted into the cyanine dye [B] with delocalized electrons which give rise to a red-shifted band with narrow half-band width ($\lambda_{\max} \approx 515$ nm). The coupling of two such cyanine dye chromophores gives rise to an electronic spectrum with a rare double maximum. The CD spectrum exhibits an intense negative couplet with $A = 462$. That the integrated areas or rotational strength of the negative and positive CEs are comparable is a manifestation of the ‘sum rule’, which states that summation of the positive and negative rotational strengths over the entire CD spectrum should be zero. The ‘sum rule’ is one of the requirements of the exciton

Figure 3 (a) UV-visible spectra of mono-Schiff base [A] and monocyanine dye [B] in CH_2Cl_2 ; (b) UV-visible and CD spectra and rotational strength R in cgs units of the biscyanine dye derivative of (1*S*, 2*S*)-*trans*-1,2-cyclohexanediamine [C] in CH_2Cl_2 2-TFA.

coupling mechanism. The observed regional sum rule, instead of a sum rule covering the entire CD range, is due to the well-separated cyanine dye maxima. In order to emphasize the similarity between electronic and chiroptical spectroscopy, the term 'exciton-coupled CD' rather than 'exciton chirality CD' is used in the following.

Chromophores for Exciton-Coupled CD

Some aspects of practical importance are summarized as follows:

1. Sample amount: μg scale.
2. Solvent: acetonitrile, methylcyclohexane. Alcoholic solvents should be used with caution when dealing with acylated substrates because of the possibility of ester exchange.
3. Any chromophore with strong intensity and known direction of μ can be used.
4. The sign of the couplet or 'split CD' is determined by the absolute sense of twist of μ .

5. Amplitude A is proportional to ϵ^2 , or to a first approximation A and ϵ have a linear relation.
6. Amplitude A is inversely proportional to the square of R , the interchromophoric distance.
7. Additivity relation holds for A values in case of identical chromophores, and for the entire CD curves when the interacting chromophores are different (see below).
8. There is no exciton coupling when the angles of interacting μ s are 0° or 180° ; in 1,2-bisacylates, the A value is maximum when the projection angle of interacting μ is $\sim 70^\circ$.
9. The interacting chromophores do not have to be identical. Moreover, they do not have to be in the same molecule, e.g. a ligand and its receptor could also interact and give exciton-coupled CD. Chromophores are introduced into chiral molecules lacking suitable chromophores. When only one chromophore is present in the substrate molecule, the newly introduced chromophore is selected so that its absorption maximum will be close to that of the preexisting chromophore.

The chromophores used for determining absolute configuration or conformation by exciton-coupled CD should have intense $\pi \rightarrow \pi^*$ transitions with a known direction of the coupled transition moments; thus chromophores with high symmetry are more suited. Some chromophores referred to in this section are summarized in Table 2.

The UV spectra of *para*-substituted benzoates and the direction of the transition moments are shown in Figure 1. Among the *para*-substituted benzoates, *p*-dimethylamino-benzoate (Table 2, [3]), is highly recommended because of the red-shifted maximum and large ϵ value. *Ortho*- and *meta*-substituted benzoates are not suited because their transition moments are not parallel to the alcoholic C–O bond; consequently, the exciton chirality will depend on the conformation around the C–O bond. *para*-Substituted benzoyl chromophores can be used for derivatizing *primary* amino groups, e.g. the intramolecular CT band of the benzamido group, $\lambda_{\text{max}} \approx 225 \text{ nm}$ ($\epsilon = 11\,200$), is again polarized along the long axis of the chromophore; however, for *sec*-amino groups the benzamido chromophores cannot be used unless the conformation around the C–N bond is established. The chromophore of 2,3-naphthalenedicarboximide [12] exhibits an intense $^1\text{B}_u$ transition around 260 nm, which is polarized along the long axis of the chromophore. This makes it ideally suited for exciton coupled CD because the long axis-polarized $^1\text{B}_u$ transition moment is exactly parallel to the C–N bond of the amine moiety; the intense ϵ and its fluorescence are further attributes (see below). Since the maxima of benzamido-2,3-naphthalenedicarboximide [12] and benzoate chromophores [1]–[4] are close to one another, combination of

Table 2 Absorption maxima and intensities of some chromophores used for derivatizations of hydroxyl and amino groups

Chromophore	Type	Chromophore	Type		
Primary and secondary OH					
[1]	 X = H	229 nm 15 300 (EtOH)	[14]	 X = OMe	333 nm 40 400 (MeOH)

[12]	<i>Selective for primary NH₂</i> 	258 nm 64 000 (CH ₃ CN)			
[13]	<i>Red-shifted for OH</i>  NMe ₂	360 nm 31 000 (MeCN)			

these chromophores is useful for determining the absolute configuration of amino alcohols.

Dienes, Enones, Ene-Esters, Ene-Lactones, Diene-Esters, Other Benzenoids

The transition moments of the $\pi\text{-}\pi^*$ band or conjugated dienes, enones, etc., are almost parallel to the long axis of chromophores (Figure 4). Phenylacetylene and benzonitrile chromophores with their intramolecular CT bands around 230 nm are also ideally suited because their CT transitions are polarized exactly parallel to the long axis of chromophores.

Polyacenes

As depicted in Figure 2a, the 1B_b transition of polyacene chromophores is ideally suitable for observing exciton coupled CD. See below for a description of the fluorescent 2-anthroate chromophore.

Examples of Exciton-Coupled CD and Natural Products

The CD of the plant hormone abscisic acid exhibits a positive couplet arising from the enone–dienoic acid coupling (directions of electric transition moments are shown by thick lines). The positive twist between these

Figure 4 Examples of natural products exhibiting an exciton-coupled CD.

two moieties shown in **Figure 4** directly indicates that the absolute configuration of the *tert*-OH is pointing down, or α . Similarly, the negative couplet of dendryphiellin F shows the dienoate side-chain to be β whereas that of manumycin shows the triene amide chain to be α . In the case of lithospermic acid, hydrolysis of its heptamethyl ether followed by *p*-bromophenacylation yielded derivative A, while methanolysis of the same heptamethyl ether gave fragment B. Subtraction of the CD of B from that of A gave a negative couplet; moiety B within the structure of A is indicated by the dotted rectangle. This difference CD shows that the coupling between the two bromophenacyl groups is negative. This defines the helicity between the two ester side-chains in lithospermic acid and hence its absolute configuration. As in any other spectroscopy, difference CD offers a powerful tool for extracting the necessary information hidden in a far more complex structure or a ligand–receptor complex.

Chromophores with Intense Absorptions

The A values of split CD curves are proportional to the absorption intensity ϵ of the chromophore. Hence the stronger the absorption the larger is the A value or the more sensitive is the measurement. The 2-anthorate chromophore (**Table 2**, [8]) with an exceptionally intense absorption is a powerful chromophore for exciton-coupled CD measurements. The 2-anthroate and 2-naphthoate [6] chromophores are of lower symmetry than *para*-substituted benzoates [1]–[4]; however, in both cases the orientation of the strong electric transition moment, 1B_u , is almost parallel to the long axis of the chromophore and therefore almost parallel to the C–O bond (**Figure 5**). Moreover, its strong fluorescence not only facilitates microscale manipulations but also should make it attractive for application for fluorescence CD (FDCD). The terminal acyclic 1,2-diol is a common moiety in many natural products and synthetic intermediates and hence assignment of the absolute configuration of the chiral centre is important. Derivatization of (2*S*)-1,2-propanediol with anthroylimidazole furnishes the bisanthroate with a positive CD bisignate curve (MeCN) at 263 nm with $A = +190$. Three distinct conformations A, B and C are conceivable for the bisanthroate. A and B lead to opposite CD exciton couplets, whereas exciton coupling in conformer C should be almost zero and therefore this conformer can only influence the amplitude and not the sign of the bisignate curve. Of the remaining two, B is not expected to contribute much because of the extra steric interactions between the methyl and the chromophores. That conformer A is the major form is supported by NMR

Figure 5 Conformations and UV and CD spectra (in MeCN) of bis-2-anthroyl-(2*S*)-1,2-propanediol.

coupling constants of $J_{1,2} = 6.8$ Hz (*trans*) and 3.7 Hz (*gauche*). The very intense UV is reflected in the large A value, which is almost 10-fold that of bis-*p*-bromobenzoate [2], i.e. +21 (in EtOH).

Pairwise Additivity Relation in Exciton-Coupled CD

An aspect of fundamental importance in exciton-coupled CD is the principle of pairwise additivity. Although Brewster and Kauzmann proposed the 'principle of pairwise interactions as a basis for an empirical theory of optical rotatory power' in 1961, it was not possible to secure experimental data to prove this since they were addressed to rotations at 589 nm (Na D-line), where values are not only extremely small but also represent summation of contributions of all stereogenic centres. However, subsequent experimental results have

established that the additivity relation holds for both monochromatic systems and bichromophoric systems.

Pairwise Additivity in Systems Containing Identical Chromophores

The amplitude A of the split CD curve for a compound containing two or more identical chromophores can be approximated by the summation of each interacting basis pair. Thus, in a trischromophoric system containing three identical chromophores I, II and III, the observed amplitude can be approximated by the sum of three interacting bischromophoric pairs (basis pairs): $A_{\text{total}} = A_{\text{I,II}} + A_{\text{II,III}} + A_{\text{I,III}}$. This is illustrated for a sugar acylate containing four *p*-bromobenzoates in **Figure 6**. Six interacting pairs of benzoates are present in this derivative, 2,3-, 2,4-, 2,6-, etc. The A values of the six pairs of *p*-bromobenzoates are shown in the table in **Figure 6**; the summation gives a value of +112, which is in excellent agreement with the experimental value of +100. The A values (i.e. constants) of all 12 conceivable pairs for hexopyranosides have been measured and tested against 42 cases of bis-, tris- and tetrakis-acylates and in all cases excellent agreement is seen. This additivity relation is also corroborated by theoretical calculations. The A values for *O*-acylates and *N*-acylates are identical, and hence they are applicable to all hexopyranosides (but not to *N*-acetyl sugars since the confirmation of the acylated *N*-acetyl bond is not known). The additivity principle also leads to a simple microscale method for determining the branching point in oligosaccharides, namely the sugars are permethylated, hydrolysed and the liberated hydroxyls which are tags of the linkage point are bromobenzoylated; each sugar benzoate is then identified from the A value (microgram level).

The pairwise additivity relation also holds for *p*-phenylbenzylates [11], thus showing that the conformation of the benzylate closely resembles that of the

benzoate; the benzylates can readily be oxidized to the corresponding *p*-phenylbenzoates [5], which give rise to another set of data. The advantage of benzylates is that they can derivatize hindered OH groups, including tertiary.

Pairwise Additivity in Systems Containing Two Different Chromophores

Two different chromophores can still exhibit exciton coupling when the absorption maxima differ by ~ 100 nm. Furthermore, the pairwise additivity relation has been shown to hold for systems containing two different chromophores, as exemplified in **Figure 7** for the α -methyl galactopyranoside Gal CCBB substituted with *p*-bromobenzoate ($\lambda_{\text{max}} = 245$ nm) at C-2,3 and *p*-methoxycinnamate ($\lambda_{\text{max}} = 311$ nm) at C-4,6. The four-symbol descriptor designates the substituents at positions 2, 3, 4 and 6, their sequence corresponding to the above order of locants: A = *O*-acetyl, C = *O*-(4-methoxycinnamoyl) and B = *O*-(4-bromobenzoyl). The CD of the six galactosides containing the interacting basis sets are also shown in **Figure 7**. As shown in **Figure 7a**, there is excellent overlap between the experimental and calculated curves. This agreement holds for all permutations of the galactose, glucose, mannose series, desoxy sugars and amino sugars with primary amino groups, a total of 150 cases. These 150 characteristic curves could provide valuable data for the development of an alternative means to conventional methylation analysis of oligosaccharides by tagging free hydroxyls as bromobenzoates or phenylbenzylates, and then derivatizing the hydroxyl groups liberated upon methanolysis. This approach requires no reference sample and, moreover, would also establish the absolute stereochemistry of the individual sugar moieties. As the additivity relation holds for other coupled systems involving various multichromophoric systems, including cage structures, its proper application greatly expands the utility of exciton-coupled CD.

Figure 6 Amplitudes and methyl 2,3,4,6-tetrakis [O-(*p*-bromobenzoyl)]- β -D-galactopyranoside, experimental (in MeOH) and calculated.

Allylic and Homoallylic Alcohols, Cyclic and Acyclic

As chromophores with a difference in λ_{max} of ~ 100 nm can still couple, this means that the observation of only one branch of the couplet suffices to determine the absolute configuration. Such a case is the allylic benzoates, where the sign of the first CE ascribable to the benzoate, $\lambda_{\text{max}} = 229$ nm [a] represents the chirality between the benzoate chromophore and the double bond; it is not necessary to observe the CE arising from the 195 nm double bond absorption. Thus the positive CE of steroid

Figure 7 (a) Experimental (solid line) and calculated sum CD spectra (dashed line) of α -methyl galactopyranoside 2,3-bis-*p*-methoxycinnamate 4,6-bis-*p*-bromobenzoate (GalCCBB). (b)–(g) six experimental pairwise exciton-coupled CDs of four interacting chromophores in GalCCBB.

[a] shown in Figure 8 reflects the positive twist between the 7β -benzoate and the 5,6-ene. The CD of a series of acyclic allylic alcohols with established configurations, [b]–[e], show that the relation can be extended to acyclic cases. In this case, the signs of CEs are rationalized by the most stable conformer of the allylic acylates in which the allylic hydrogen adopts a *syn* relation with the double bond [f] so that the sign of the ‘couplet’ is determined by the twist between the benzoate and the double bond, as in cyclic allylic benzoates. Unsubstituted benzoates are preferred in these studies since the maxima are closest to the ene maxima.

The CE of homoallylic benzoate [g] is also in accord with the chirality, although its intensity is lower than that of allylic benzoate [1]. The additivity again holds, as seen for steroid derivative [h]. Application of this additivity between allylic and homoallylic benzoates was used to determine the configuration of moiety [i] in an acyclic natural product.

Acyclic 1,2-, 1,3- and Mixed 1,2-/1,3-Acyclic Polyols and Aminopolyols

Acyclic 1,2-, 1,3- and mixed 1,2-/1,3-polyols and aminopolyols are frequently present in natural products, including polyene macrolides. Because of the lack of general methods for determining their relative and absolute configurations, the stereostructures of most of them remain undetermined. However, a library of such polyols up to pentaols is now available for all permutations of stereorelations; in this library, the primary hydroxyl or amino groups are derivatized by the anthrolyl chromophore [j] while the other hydroxyl or amino groups are derivatized by [f]; as in other cases, the CD properties of O and N derivatives are very similar so that the same set of data can be used. Figure 9 shows that the CD of the mixed polyol moiety present in the hopanoid [I] is superimposable on that of the reference mixed polyol derivative [II] in two solvents, the nonpolar

methylcyclohexane (MC) and more polar acetonitrile (AN); this determines the absolute configuration of the side-chain on a microgram scale.

Exciton-Coupled CD Due to Pre-existing Chromophores

The well-known bitter principle of the wood of *Quassia amara* L., quassin, has two enone chromophores within its structure shown in **Figure 10**. Accordingly, its CD exhibits

a typical couplet at 266 nm ($\Delta\epsilon = +10.4$)/242 nm ($\Delta\epsilon = -9.5$) arising from the twist between the two chromophores, thus directly establishing its absolute configuration as depicted. The excellent agreement between the CD calculated from the UV and geometry of the molecule and observed CD not only establishes the absolute configuration of quassin but also proves that the observed CD of quassin around 250 nm is due to exciton coupling. This conclusion is consistent with the absolute configurational assignment of quassin based on biosynthetic considerations and X-ray analysis of biogenetically related

Figure 10 Absolute configuration of quassin.

compounds. The negative CE at 330 nm is due to the $\pi \rightarrow \pi^*$ transition of the enone chromophores. It should be noted that despite the negative 330 nm CE, the optical rotation at the sodium D-line (589 nm) is positive: $[\alpha]_D + 34.5^\circ$ (c 5.09, CHCl_3). Therefore, the D-line rotation, which is simply the reading at 589 nm taken in the optical rotatory dispersion (ORD) mode, is governed by the intense positive Cotton effect at 266 nm. The CD of abscisic acid described in **Figure 4** is very similar to that of quassin.

The clinically important anticancer drug vinblastine also incorporates two chromophores, the indole and indoline moieties, which are coupled through space. The biologically active molecule is that depicted in **Figure 11**, while its biologically inactive diastereomer at C-16' has a different CD. The UV spectrum has an intense band at 214 nm ($\epsilon = 46\,200$) with a shoulder at 228 nm which arises from the 1B_a transitions of the indoline (217 nm) and indole (225 nm) chromophores; this is accompanied by the intense positive CD couplet in this region. The weaker 260 nm ($\epsilon = 15\,000$) band is due to the 1L_a transition of the indoline moiety, while the overlapping bands at 293 nm ($\epsilon = 10\,500$) are from the 1L_a and 1L_b transitions of the indole chromophore and the 1L_b transition of the indoline chromophore. Theoretical calculations of the UV and CD of the strong bands centred around 220 nm using atomic coordinates based on MM2 and SCF-CI-DV MO are in excellent

Figure 11 Experimental (in MeCN) and calculated CD spectra of vinblastine.

agreement with the observed CD couplet, thus proving that the couplet, which is used empirically to differentiate the bioactive isomer from the inactive isomer, is indeed due to exciton coupling between the two moieties.

Red-Shifted Chromophores for Hydroxyl Groups

Since the natural substrate itself frequently contains a chromophore or may be contaminated with some UV-absorbing substance, the use of chromophores with absorbance shifted to the red is advantageous in order to avoid complications due to unnecessary interactions. Chromophores [13]–[17] and [18]–[21] (**Table 2**) with red-shifted intense maxima can be used for derivatizing hydroxyl and amino groups, respectively. **Figure 12** lists the UV–visible and CD data for derivatives of 1(*R*),2(*R*)-cyclohexanediol; in all cases the Λ values are intense and the spectra appear in regions that usually are transparent.

Figure 13 demonstrates the advantage of using such chromophores. The yew tree constituent taxinine shares the same skeleton as taxol and taxotere, prominent anticancer compounds. The highly strained enone group of the skeleton shows a strong CE at 262 nm arising from a $\pi \rightarrow \pi^*$ transition and a weaker CE at 354 nm from the $\pi \rightarrow \pi^*$ transition. The 262 nm band overlaps with conventional chromophores. However, [17] with its maximum at 410 nm is completely removed from the enone absorptions. Hence the C-9 and C-10 bis-esters formed from this chromophore show typical exciton couplet in a region remote from enone absorption. The negative couplet agrees with the absolute configuration of the taxane skeleton deduced by other means, including exciton-coupled CD of a derivative using a more conventional chromophore, the interpretation of which was not as clearcut.

Figure 12 UV-visible spectra of chromophores [13], [15], [16], [17] and CD spectra of diesters formed from 1(*R*), 2(*R*)-cyclohexane-diol, in MeCN.

Figure 13 UV-visible and CD spectra of taxinine [1] and its bis-ester formed with chromophore [17] in MeCN.

Red-Shifted Chromophores for Amino Groups

Chromophores [18] and [19] (Table 2) are simply imines or Schiff bases formed in high yield by reacting primary amines with *p*-dimethylaminobenzaldehyde and *p*-dimethylaminocinnamaldehyde under mild conditions

and in the presence of unprotected hydroxyl groups. Addition of a drop of trifluoroacetic acid to the UV or CD cell converts them into protonated Schiff bases, which exhibit intense and very sharp absorptions in the red due to their cyanine dye structure; moreover, addition of a small amount of water will hydrolyse the protonated Schiff base bond, leading to recovery of the

starting amine. The derivative of acosamine is prepared by derivatizing the amino group and then the hydroxyl group with the respective chromophores [20] and [14] (**Figure 14**). The exciton couplet is intense with an amplitude of 110. Acidification shifts the couplet to longer wavelength because of the shift of the imine band from 360 to 460 nm; however, the intensity decreases owing to the diminished overlap between the chromophores, from 330/360 nm in the neutral form to 330/460 nm in the protonated derivative. If the coupling is between two protonated Schiff base moieties, i.e. between two cyanine dyes, then the couplet becomes well-separated and is greatly intensified (see **Figure 3**).

Porphyrins, a Very Promising Chromophore

The porphyrin chromophores exemplified by [22] and [23] are powerful chromophores for exciton-coupled CD because of the very intense ϵ of the red-shifted and sharp Soret band at 418 nm (**Figure 15**). The effective direction of the electric transition moment can be regarded as running parallel to the C–O bond of the derivatized alcohol as in any other *para*-substituted benzoates. The solubilities can be modified over a wide range through

Figure 14 CD of acosamine derivatized with chromophores [14] and [20]/[21], in MeCN.

Figure 15 Tetraarylporphyrins.

the appended aromatic rings at C-10, -15 and -20; the triphenyl derivative depicted is hydrophobic whereas a trimethylpyridinium derivative is hydrophilic. Thus the pairing of a hydrophobic or hydrophilic porphyrin derivative with the polarity of the solvent will lead either to intramolecular coupling or to intermolecular stacking. This results in great versatility in the use of porphyrins in exciton-coupled CD. Attachment of trimethylpyridinium porphyrin to a brevetoxin B derivative, a molecule with a rigid skeletal structure, shows intramolecular exciton coupling even over a distance of $\sim 40\text{--}50$ Å (in methanol). The very efficient intramolecular coupling arising from the intense ϵ is illustrated in **Figure 16**. The amplitude of the positive couplet of the 3,6-bis-substituted steroid is +675 at an interchromophoric distance of 13.8 Å; the amplitude of the 3,6-bis-*p*-dimethylamino-benzoate [3], in contrast, is +89. Zinc porphyrins (e.g. [23]) are even more promising because of their more intense absorptions; furthermore, the ability of the central metal atom to coordinate with amino groups adds further versatility to their use in exciton-coupled CD.

Exciton-Coupled Fluorescence CD

This field is newer. However, exciton-coupled CD detected either by absorption (conventional CD) or by emission both give the same CD curve, as shown in **Figure 17**. The greatest advantage of fluorescence-based CD exciton coupling is that the sensitivity is increased 50–100-fold under favourable conditions involving two identical fluorophores, and that it selectively records the coupling between fluorophores and is not perturbed by nonfluorescent chromophores. However, this field requires further studies, from the viewpoint of both theory and application.

Quantum Mechanical Theory of Exciton-Coupled CD

CD Spectra and Rotational Strength of Cotton Effect

The rotational strength R , a theoretical parameter representing the sign and intensity of a CD Cotton effect, is expressed in eqn [1] and is obtained from the observed CD spectra.

$$R = 2.296 \times 10^{-39} \int \Delta\epsilon(\sigma)/\sigma d\sigma \quad (\text{cgs units}) \quad [1]$$

where σ is wavenumber.

The rotational strength R is also formulated by the Rosenfeld equation:

$$R = \text{Im}\{\langle o|\mu|a\rangle \cdot \langle a|M|o\rangle\} \quad [2]$$

Figure 16 Porphyrin/porphyrin exciton coupling and UV-visible and CD spectra in CH_2Cl_2 ($c = 1.0 \mu\text{M}$) of 5 α -androstane-3 α ,17 β -diol bis[*p*-(10',5',20'-triphenyl-5'-porphyrinyl)benzoate] (solid line) and UV-visible spectrum of 5-(4'-carboxyphenyl)-10,15,20-triphenylporphyrin in CH_2Cl_2 (dashed line).

Figure 17 Comparison of conventional CD (solid line) with the CD converted from FDCD (dashed line) for 5 α -cholestane-3 β ,6 α -diol bis(2-anthroate) in MeCN.

where Im denotes the imaginary part of the terms in brackets, $\langle \rangle$ denotes the integration over configuration space and μ and M are operators of electric and magnetic moment vectors, respectively. The dot $\cdot$ stands for scalar

product of two vectors and o and a are wavefunctions of ground and excited states, respectively. Thus the rotational strength R is equal to the imaginary part of the scalar product of electric and magnetic transition moments.

Provided a CD Cotton effect is approximated by a Gaussian distribution, eqn [3] is obtained:

$$\Delta\varepsilon(\sigma) = \Delta\varepsilon_{\max} \exp\{ -[(\sigma - \sigma_o)/\Delta\sigma]^2 \} \quad [3]$$

where $\Delta\varepsilon_{\max}$ is the maximum intensity of the Cotton effect, σ_o is the central wavenumber of the Cotton effect, and $\Delta\sigma$ is the standard deviation of the Gaussian distribution. From eqns [1] and [3]:

$$R = 2.296 \times 10^{-39} \sqrt{\pi \Delta\varepsilon_{\max} \Delta\sigma / \sigma_o} \quad [4]$$

From eqns [3] and [4], the calculated CD curve is formulated as

$$\Delta\varepsilon(\sigma) = [\sigma_o / (2.296 \times 10^{-39} \sqrt{\pi \Delta\sigma})] \times R \exp\{ -[(\sigma - \sigma_o)/\Delta\sigma]^2 \} \quad [5]$$

where $\Delta\sigma$ can be evaluated from observed UV-visible spectra. Provided the rotational strength R is calculated by eqn [2], the CD spectrum can be reproduced by theoretical calculation.

UV-Visible Spectra and Dipole Strength

The dipole strength D representing the intensity of UV-visible bands is estimated from the observed spectra:

$$D = 9.184 \times 10^{-39} \int \varepsilon(\sigma) / \sigma d\sigma \quad [6]$$

The dipole strength is formulated as

$$D = \{ \langle o | \mu | a \rangle \}^2 \quad [7]$$

Hence, the dipole strength D is equal to the square of the electric transition moment μ .

Molecular Exciton Theory of a Binary System with Two Chromophores

In the exciton coupling system composed of two identical chromophores i and j , exciton wavefunctions are expressed as eqns [8] and [9], where each chromophore undergoes excitation $o \rightarrow a$

$$\text{ground state: } \phi_{io}, \phi_{jo} \quad [8]$$

$$\text{excited state: } \phi_{ia}, \phi_{ja} \quad [9]$$

The Hamiltonian operator of the coupling system is formulated as:

$$H = H_i + H_j + H_{ij} \quad [10]$$

where H_i and H_j are the Hamiltonians of groups i and j , respectively, and H_{ij} is the interaction energy term between two groups i and j .

Wavefunction and Energy of Ground State

The ground-state wavefunction and energy of a binary system are

$$\Psi_o = \phi_{io} \phi_{jo} \quad [11]$$

$$E_o = 0 \quad [12]$$

Wavefunction and Energy of Singly Excited State

The singly excited state of the binary system splits into two energy levels, α and β states. For the α -state,

$$E^\alpha = E_a - V_{ij}, \Psi_a^\alpha = (1/\sqrt{2}) \{ \phi_{ia} \phi_{jo} - \phi_{io} \phi_{ja} \} \quad [13]$$

where V_{ij} is the interaction energy between two groups i and j and is approximated by a point dipole approximation method:

$$V_{ij} = \mu_{ioa} \mu_{j oa} R_{ij}^{-3} \{ \mathbf{e}_i \cdot \mathbf{e}_j - 3(\mathbf{e}_i \cdot \mathbf{e}_{ij})(\mathbf{e}_j \cdot \mathbf{e}_{ij}) \} \quad [14]$$

where μ_{ioa} , $\mu_{j oa}$ and R_{ij} are absolute values of vectors μ_{ioa} , $\mu_{j oa}$ and R_{ij} , respectively; $\mathbf{e}_i$, $\mathbf{e}_j$ and $\mathbf{e}_{ij}$ are unit vectors of μ_{ioa} , $\mu_{j oa}$ and R_{ij} , respectively. For μ_{ioa} , $\mu_{j oa}$ and R_{ij} see eqns [17] and [29].

For the β -state,

$$E^\beta = E_a + V_{ij}, \Psi_a^\beta = (1/\sqrt{2}) \{ \phi_{ia} \phi_{jo} + \phi_{io} \phi_{ja} \} \quad [15]$$

These equations indicate that the binary system has two electronic transitions $o \rightarrow \alpha$ and $o \rightarrow \beta$, in the UV-visible spectrum. If $V_{ij} > 0$, the α -state is lower in energy than the β -state, and therefore the transition $o \rightarrow \alpha$ locates at longer wavelengths and the transition $o \rightarrow \beta$ at shorter wavelengths.

Electric Transition Moment of a Binary System

The electric dipole moment operator μ of a whole system is defined as

$$\mu = \sum \mu_i = \sum \sum e r_{is} \quad [16]$$

where μ_i is the electric dipole moment operator of group i , e is the elementary charge and r_{is} is the distance vector of electron s in group i from the origin. The electric transition moment $\langle a | \mu | o \rangle^\alpha$ of the transition $o \rightarrow \alpha$ is expressed as

$$\begin{aligned} \langle o | \mu | a \rangle^\alpha &= \mu_{oa}^\alpha = \int \Psi_o \mu \Psi_a^\alpha d\tau \\ &= (1/\sqrt{2})(\mu_{ioa} - \mu_{j oa}) \end{aligned} \quad [17]$$

where $\mu_{ioa} = \int \phi_{io} \mu_i \phi_{ia} d\tau_i$ and $\mu_{j oa} = \int \phi_{jo} \mu_j \phi_{ja} d\tau_j$. These are electric transition moments of the transition $o \rightarrow a$ in

groups i and j , respectively. The electric transition moment of the transition $o \rightarrow \beta$ is similarly expressed as

$$\begin{aligned} \langle o | \mu | a \rangle^\beta &= \mu_{oa}^\beta = \int \Psi_o^* \mu \Psi_a \beta \, d\tau \\ &= (1/\sqrt{2})(\mu_{ioa} + \mu_{joa}) \end{aligned} \quad [18]$$

Magnetic Transition Moment of a Binary System

The magnetic moment operator $\mathbf{M}$ of a whole system is formulated as

$$\mathbf{M} = \Sigma \mathbf{M}_i = (e/2mc) \Sigma \Sigma \mathbf{r}_{is} \times \mathbf{p}_{is} \quad [19]$$

where m is the mass of an electron, c is the velocity of light, $\mathbf{p}_{is}$ is the linear momentum of electron s in group i , and $\times$ represents the vector product of two vectors.

The magnetic moment operator is further changed as

$$\mathbf{M} = (e/2mc) \Sigma \mathbf{R}_i \times \mathbf{p}_i + \Sigma \mathbf{m}_i \quad [20]$$

where $\mathbf{R}_i$ is the distance vector of group i from the origin and $\mathbf{p}_i$ and $\mathbf{m}_i$ are linear momentum and internal magnetic moment operators of group i , respectively. The magnetic transition moment $\langle a | \mathbf{M} | o \rangle^\alpha$ of the excitation $o \rightarrow \alpha$ is calculated as

$$\begin{aligned} \langle a | \mathbf{M} | o \rangle^\alpha &= \int \Psi_a^* \mathbf{M} \Psi_o \, d\tau \\ &= (1/\sqrt{2}) \{ (e/2mc) \mathbf{R}_i \times \mathbf{p}_{iao} + \mathbf{m}_{iao} \\ &\quad - (e/2mc) \mathbf{R}_j \times \mathbf{p}_{jao} - \mathbf{m}_{jao} \} \end{aligned} \quad [21]$$

where $\mathbf{p}_{iao}$ and $\mathbf{m}_{iao}$ are linear momentum and internal magnetic moment of group i , respectively.

For the linear momentum of a group, the next equation is very useful:

$$\mathbf{p}_{oa} = -(2\pi i m c / e) \sigma_o \mu_{oa} \quad [22]$$

where i is the symbol for 'imaginary', σ_o is excitation energy expressed in wavenumber units and μ_{oa} is electric transition moment of transition $o \rightarrow a$. Applications of this equation to group i :

$$\mathbf{p}_{iao} = (2\pi i m c / e) \sigma_o \mu_{ioa} \quad [23]$$

Accordingly,

$$\begin{aligned} \langle a | \mathbf{M} | o \rangle^\alpha &= (1/\sqrt{2}) \{ i\pi \sigma_o \mathbf{R}_i \times \mu_{ioa} - i\pi \sigma_o \mathbf{R}_j \\ &\quad \times \mu_{joa} + \mathbf{m}_{iao} - \mathbf{m}_{jao} \} \end{aligned} \quad [24]$$

In a similar way, the magnetic transition moment of excitation $o \rightarrow \beta$ is calculated as

$$\begin{aligned} \langle a | \mathbf{M} | o \rangle^\beta &= (1/\sqrt{2}) \{ i\pi \sigma_o \mathbf{R}_i \times \mu_{ioa} + i\pi \sigma_o \mathbf{R}_j \\ &\quad \times \mu_{joa} + \mathbf{m}_{iao} + \mathbf{m}_{jao} \} \end{aligned} \quad [25]$$

Dipole Strength a Binary System

The dipole strength D^α for the excitation $o \rightarrow \alpha$ is expressed as

$$D^\alpha = (1/2)(\mu_{ioa} - \mu_{joa})^2 \quad [26]$$

Similarly,

$$D^\beta = (1/2)(\mu_{ioa} + \mu_{joa})^2 \quad [27]$$

Rotational Strength a Binary System

The rotational strength R^α of the α -state is calculated from eqns [2], [17] and [24]:

$$\begin{aligned} R^\alpha &= \text{Im} \{ \langle o | \mu | a \rangle^\alpha \cdot \langle a | \mathbf{M} | o \rangle^\alpha \} \\ &= (1/2) \text{Im} \{ (\mu_{ioa} - \mu_{joa}) \cdot (\mathbf{m}_{iao} - \mathbf{m}_{jao}) \} \\ &\quad + (1/2) \pi \sigma_o \mathbf{R}_{ij} \cdot (\mu_{ioa} \times \mu_{joa}) \end{aligned} \quad [28]$$

where $\mathbf{R}_{ij}$ is the interchromophoric distance vector from group i to group j , and is defined as

$$\mathbf{R}_{ij} = \mathbf{R}_j - \mathbf{R}_i \quad [29]$$

Similarly,

$$\begin{aligned} R^\beta &= \text{Im} \{ \langle o | \mu | a \rangle^\beta \cdot \langle a | \mathbf{M} | o \rangle^\beta \} \\ &= (1/2) \text{Im} \{ (\mu_{ioa} + \mu_{joa}) \cdot (\mathbf{m}_{iao} + \mathbf{m}_{jao}) \} \\ &\quad - (1/2) \pi \sigma_o \mathbf{R}_{ij} \cdot (\mu_{ioa} \times \mu_{joa}) \end{aligned} \quad [30]$$

In the case of $\pi \rightarrow \pi^*$ transitions of common molecules, internal magnetic transition moments $\mathbf{m}_{iao}$ and $\mathbf{m}_{jao}$ are negligible. Therefore, rotational strengths are approximated as

$$R^\alpha = +(1/2) \pi \sigma_o \mathbf{R}_{ij} \cdot (\mu_{ioa} \times \mu_{joa}) \quad [31]$$

$$R^\beta = -(1/2) \pi \sigma_o \mathbf{R}_{ij} \cdot (\mu_{ioa} \times \mu_{joa}) \quad [32]$$

These equations indicate that the Cotton effects of α - and β -states have equal intensity but are of opposite signs, and therefore the exciton CD satisfies the sum rule:

$$\Sigma R_A = R^\alpha + R^\beta = 0 \quad [33]$$

The rotational strength is proportional to the triple product of interchromophoric distance and electric transition moments of groups i and j . Therefore, provided chromophores exhibiting intense $\pi \rightarrow \pi^*$ transitions are employed, intense exciton CD Cotton effects are observable. The rotational strengths of exciton CD satisfy the origin independence as shown in eqn [32].

CD Spectra of *N*-mer and Dimer: Quantitative Definition of CD Exciton Coupling

The exciton theory is also applied to UV-visible and CD spectra of *N*-mers having *N* identical chromophores. When *N* chromophores undergoing intense π - π^* transitions ($o \rightarrow a$) interact with one another, the excited state splits into *N* energy levels. The wavenumber σ_k of the *k*th excitation is expressed as

$$\sigma_k - \sigma_o = 2 \sum \sum C_{ik} C_{jk} V_{ij} \quad [34]$$

where the coefficients C_{ik} and C_{jk} can be obtained by solving the secular equation of *N*th order. The rotational strength of R^k is similarly formulated as

$$R^k = -\pi \sigma_o \sum \sum C_{ik} C_{jk} \mathbf{R}_{ij} \cdot (\mu_{ioa} \times \mu_{j oa}) \quad [35]$$

For the *N*-mer, the CD curve is formulated as

$$\Delta \varepsilon(\sigma) = \{ \sigma_o / (2.296 \times 10^{-39} \sqrt{\pi \Delta \sigma}) \} \sum R^k \times \exp\{ -((\sigma - \sigma_k) / \Delta \sigma)^2 \} \quad [36]$$

The Taylor expansion of eqn [36] against $\sigma_k / \Delta \sigma$ around $\sigma_o / \Delta \sigma$ yields the second term of the expansion as

$$\Delta \varepsilon(\sigma) = \{ 2 \sigma_o / (2.296 \times 10^{-39} \sqrt{\pi \Delta \sigma}) \} \times \exp\{ -((\sigma - \sigma_o) / \Delta \sigma)^2 \} \{ (\sigma - \sigma_o) / \Delta \sigma \} \times \sum R^k \{ (\sigma_k - \sigma_o) / \Delta \sigma \} \quad [37]$$

From eqns [34], [35] and [37], the CD equation of the *N*-mer is obtained:

$$\Delta \varepsilon(\sigma) = \{ 4 \sqrt{\pi \sigma_o^2} / (2.296 \times 10^{-39} \Delta \sigma^2) \} \times \{ (\sigma_o - \sigma) / \Delta \sigma \} \exp\{ -((\sigma_o - \sigma) / \Delta \sigma)^2 \} \times \sum \{ \sum \sum C_{ik} C_{jk} \mathbf{R}_{ij} \cdot (\mu_{ioa} \times \mu_{j oa}) \} \times \{ \sum \sum C_{ik} C_{jk} V_{ij} \} \quad [38]$$

In the case of a binary system, since the coefficients for the α -state are $1/\sqrt{2}$ and $-1/\sqrt{2}$, and for the β -state, $1/\sqrt{2}$ and $-1/\sqrt{2}$, eqn [38] is simplified to

$$\Delta \varepsilon(\sigma) = \{ 2 \sqrt{\pi \sigma_o^2} / (2.296 \times 10^{-39} \Delta \sigma^2) \} \times \{ (\sigma_o - \sigma) / \Delta \sigma \} \exp\{ -((\sigma_o - \sigma) / \Delta \sigma)^2 \} \times \mathbf{R}_{ij} \cdot (\mu_{ioa} \times \mu_{j oa}) V_{ij} \quad [39]$$

This is the CD equation of a binary system. The next term of eqn [39],

$$\{ 2 \sqrt{\pi \sigma_o^2} / (2.296 \times 10^{-39} \Delta \sigma^2) \} \times \{ (\sigma_o - \sigma) / \Delta \sigma \} \exp\{ -((\sigma_o - \sigma) / \Delta \sigma)^2 \} \quad [40]$$

represents an anomalous dispersion curve with positive and negative extrema. The sign and intensity of exciton CD depend on the quadruple term, $\mathbf{R}_{ij} \cdot (\mu_{ioa} \times \mu_{j oa}) V_{ij}$. Therefore, the term $\mathbf{R}_{ij} \cdot (\mu_{ioa} \times \mu_{j oa}) V_{ij}$ is adopted as the quantitative definition of exciton chirality. This term is changed to

$$\mathbf{R}_{ij} \cdot (\mu_{ioa} \times \mu_{j oa}) V_{ij} = D_{ioa} D_{j oa} R_{ij}^{-2} \mathbf{e}_{ij} \cdot (\mathbf{e}_i \times \mathbf{e}_j) \times \{ \mathbf{e}_i \cdot \mathbf{e}_j - 3(\mathbf{e}_i \cdot \mathbf{e}_{ij})(\mathbf{e}_j \cdot \mathbf{e}_{ij}) \} \quad [41]$$

where D_{ioa} and $D_{j oa}$ are transition dipole strengths of groups *i* and *j*, respectively. This equation indicates that the exciton CD amplitude is inversely proportional to the square of the interchromophoric distance R_{ij} .

Introduction and History

The far-infrared spectral region is the range of wavenumbers where one finds many of the large-amplitude anharmonic vibrations. These include both the symmetric and asymmetric internal torsional modes of many small organic and organometallic molecules, ring puckering vibrations of four- and five-membered rings, and the heavy-atom skeletal bending modes. Additionally, this is the spectral region where one finds lattice vibrations from which information is obtained on intermolecular forces that are of considerable interest to both chemists and physicists.

Historically, this region has been defined from 200 to 10 cm^{-1} , which is the region below the cutoff of CsI, where it can no longer be used as a dispersive material. Initial investigations in this spectral region began before the turn of the twentieth century in Europe, and it has always been more popular in Western Europe and Japan than in the United States. Even before the use of Fourier transform interferometers became common for this spectral region, there were several laboratories in these other countries where the far-infrared spectral region was studied almost exclusively. The first chemical applications of Fourier transform infrared (FT-IR) spectroscopy were made in the far-infrared spectral region because the interferometric instrumentation required to

obtain spectra in this region is much simpler than that needed for the mid- or near-infrared regions. The instrumental advantages in the far-infrared spectral region included a lower tolerance for the mirror drive of a Michelson interferometer, a smaller dynamic range of the interferogram and a longer sampling time, which results in a reduced number of data points.

The far-infrared spectral region initially had its inherent difficulties, such as low-energy sources, poor detectors, lack of suitable optical materials and spectral interference of water vapour. Research workers in this wavenumber area have overcome many of these difficulties and, therefore, spectral investigations in the far-infrared region have become more common. This is particularly true with the commercial availability of Fourier transform spectrometers, which routinely provide spectral data to 30 cm^{-1} with excellent signal-to-noise ratios. However, because of the absorption of water vapour in this spectral region (see **Figure 1**), it is highly desirable to have a vacuum interferometer bench.

Many of the far-infrared spectral studies for chemical information have emphasized the gas phase. This emphasis should not be interpreted as meaning that far-infrared spectral studies of solids are not important. Physicists have put interferometers to use in the study of the solid state to determine optical constants such as the index of refraction, complex indices, phase angle transmission coefficients and the electronic processes in insulation crystals, as well as the intermolecular vibrations of molecular crystals. These studies have been very important in the development of interpretative theories of solids.

With the increased ability to utilize *ab initio* calculations for predicting relative conformational stabilities, barriers to internal rotation, small ring inversions and low-wavenumber vibrations, the theoretical predictions are frequently compared with the experimental results in this spectral region. The use of either an incomplete or

Figure 1 Far-infrared spectra of (a) water vapour and (b) trifluoroacetyl fluoride.

an incorrect experimental database in comparisons with theoretical results may lead to erroneous conclusions with regard to the reliability and accuracy of the theoretical results.

Poor experimental databases with regard to the experimental determination of potential barriers and conformational equilibria arise for three basic reasons. First, there is frequently insufficient structural information in many cases. Numerous potential functions governing internal rotation of asymmetric tops (conformational interchange) have been published without the knowledge of the structures of both conformers, particularly of the high-energy conformer. It is extremely important, for the accurate experimental determination of the energy levels and potential functions, that some reasonable structural information be known about all of the exhibited conformations. Furthermore, in the absence of reliable structures determined from experimental techniques, such as those determined from microwave spectroscopy or analysis of the electron diffraction pattern, the reliability of optimized geometries determined from theory cannot be ascertained.

Second, there is frequently a lack of complementary experimental data. Owing to symmetry and the resulting selection rules, both infrared and Raman spectroscopic results are often needed to identify the high-energy and low-energy conformers. The Raman spectrum of the gas is almost always neglected, and it is not unusual to find vibrational conformational studies for which spectra are not reported for all three phases.

Third, there is often a lack of high-resolution data. The highest possible resolution available should be used to record the low-frequency spectral data. Many torsional bands are extremely sharp and, therefore, transitions may not be observed at the lower resolution. Additionally, insufficient resolution may result in misleading relative intensities of the Q branches from different energy levels.

Low-wavenumber FT-IR spectroscopy is among the most generally applicable methods used in the study of the conformers for certain types of small molecules with few substituents. Infrared spectra can, and variable-temperature experiments may, be investigated in all phases. The gas-phase band contours observed for the infrared spectra, along with Raman depolarization data, provide considerable information on the molecular symmetry of the conformers. The limitation of the vibrational spectroscopic technique is that it is best applied to relatively simple molecules that contain at least one element of symmetry, and one or perhaps no more than two portions of the molecule capable of producing different conformations upon internal rotation.

One of the earlier uses of the far-infrared spectral region was to determine the barrier to internal rotation of symmetric-top rotors. The most frequently studied molecules were those with one threefold internal rotation, and many of those studies were for methyl tops. The first indication that the rotation around single bonds was not free came from thermodynamic data in the mid-1930s. Barriers were calculated from the thermodynamic data by relating the difference in the observed and statistical entropies by tables involving the barrier height and the reciprocal of the partition function for free rotation. Later, barrier values were obtained from investigations of the microwave spectra of small molecules where the observed perturbations on the pure rotational transitions were correlated with the torsional barrier heights by either the splitting or the intensity method. The splitting method is the most exact method since it depends only on the height of the barrier and usually gives barrier values to a few percent. The microwave intensity method is frequently used for the determination of the fundamental frequencies of asymmetric rotors.

One wishes to obtain the fundamental wavenumber for the torsional mode for the gaseous molecule so that the barrier height in the isolated molecule can be ascertained. However, the dipole moment change associated with the torsional mode may be quite small, and consequently the resulting infrared band intensity may be weak. Therefore, assignments of the torsional modes of molecules in the gas were frequently in error in the initial investigations and the use of isotopic substitution is often necessary to verify the torsional assignments. Also, torsional modes that give rise to B-type infrared band contours may have bands that are very broad and ill-

defined because of unresolved excited-state transitions. In favourable cases where the torsional mode gives rise to A-type or C-type band contours with relatively strong Q branches, several excited state transitions may be resolved and not only can the barrier height be obtained but also the detailed shape of the potential well may be ascertained.

When a molecule has a far-infrared spectrum too complicated for quantitative interpretation, estimates of the barrier heights may be obtained by studying the infrared and Raman spectra of the sample in the crystalline state. At liquid-nitrogen temperature, the upper vibrational states are effectively depopulated and only the $1 \leftarrow 0$ torsional transition is observed. The barrier height may be estimated from this single experimental datum, but a detailed analysis of the shape of the potential well is not possible. Additionally, it is sometimes possible to observe the torsional mode in the solid state when it is forbidden for the gaseous molecule. Barriers obtained in the solid state are usually 10–15% higher than those for the gaseous molecules.

Internal Rotors

Internal rotors fall into two categories: symmetric and asymmetric tops. For symmetric tops, a rotation about the top-frame bond of $2\pi/n$ (where n is an integer) will bring the top to a position symmetrically equivalent to, or indistinguishable from, the original configuration. Therefore, it is usual to speak of the ‘foldness’ of the rotor in terms of n . For example, a perfluoromethyl group (CF_3) is a threefold symmetric top (local C_{3v} symmetry), and twofold rotors include $-\text{NO}_2$, $-\text{BF}_2$ and phenyl groups (local C_{2v} symmetry). When a rotation of 360° (i.e. when $n=1$) is the only operation that results in a symmetrically equivalent position for the top, the rotor is known as an asymmetric top. For the case of a symmetric frame, the top with the highest degree of symmetry prevails and, when two tops of different foldness are bonded directly to one another, the resultant foldness is the product of the two individual tops’ foldness. For instance, CH_3BH_2 would be classified as a sixfold internal rotor.

The energy minima and maxima for a symmetrical threefold group (CF_3) are 60° apart. The simplest mathematical function that will reproduce such a potential variation upon rotation is a cosine function. If the problem is assumed to be one-dimensional, the quantum-mechanical energy solutions are readily obtainable. The model employed is a rigid symmetric top (CF_3 group) attached to a rigid frame, which may be completely asymmetric. There are four rotational degrees of freedom, three for overall rotation and one for the hindered rotation of the two groups. The axis of internal rotation is usually assumed to coincide with the unique axis of the

symmetric top. Since the top has a threefold symmetry axis, the potential energy hindering rotation may be expressed by a Fourier expansion:

$$V(\phi) = \frac{V_3}{2}(1 - \cos 3\phi) + \frac{V_6}{2}(1 - \cos 6\phi) + \dots$$

where V_3 is the height of the threefold barrier; V_6 the sixfold; and so forth. A positive V_6 makes the minima narrower and the maxima broader, which results in the energy levels near the bottom of the well becoming somewhat more widely separated. A negative V_6 term has the opposite effect. Experimentally it has been found that $0 \leq V_6/V_3 < 0.05$ and $V_6 \gg V_9 \gg$ higher-order terms.

An example of the use of far-infrared spectral data for the determination of the barrier to internal rotation is given by trifluoroacetyl fluoride, CF_3CFO (Figure 1). Seven torsional transitions are clearly observed, beginning with the fundamental at 45.65 cm^{-1} and continuing to the $7 \leftarrow 6$ transition at 33.40 cm^{-1} . Utilizing an F number ($b^2/8\pi^2 I_r$ where I_r is the reduced moment of inertia of the top) of 0.5970 cm^{-1} along with the wavenumbers of these seven transitions, the V_3 value is $382 \pm 2 \text{ cm}^{-1}$ and $V_6 = 8 \pm 1 \text{ cm}^{-1}$. The intensity of the $4 \leftarrow 3$ transition and higher excited state transitions are significantly higher than expected on the basis of the Boltzmann factors because of the increased anharmonicity in the higher excited states. The statistical uncertainty is very low for both the V_3 and V_6 terms and the V_6 term is very small. This molecule is too heavy for the barrier to be determined by the microwave splitting method. Molecules with two or three equivalent rotors have also been extensively investigated, but the spectral data are much more complex and frequently there is not sufficient data to obtain values for all of the potential constants. Good barrier determination from far-infrared data requires that the internal torsional mode is not mixed (potential energy distribution) with other low-wavenumber bending modes.

The asymmetric rotor is the other type of torsional motion frequently studied. These rotors usually lead to two or more stable conformers. One of the major goals of conformational analysis is the calculation of the energy difference between the two conformers and the energy necessary for interconversion. Four types of information are required to characterize an asymmetric potential function: (1) the approximate dihedral (torsional) angle of each conformer, because the number of torsional energy levels is directly related to the number of potential minima; (2) the approximate relative enthalpy difference between the high- and low-energy conformers, since this is one of the constraints defining the potential functions; (3) the change in molecular kinetic energy as a function of torsional angle; and (4) accurate observation of torsional transition frequencies. A typical spectrum for such

Figure 2 Far-infrared spectrum of fluoroacetyl fluoride, FCH_2CFO .

a rotor is shown in **Figure 2** where the fundamental torsional mode of the *trans* conformer of FCH_2CFO is observed at 118.9 cm^{-1} with the excited torsional modes falling to lower wavenumbers to the $13 \leftarrow 12$ transition at 67.0 cm^{-1} . The fundamental torsional mode for the *cis* conformer is assigned at 52.1 cm^{-1} with five successive excited states falling to lower wavenumber with the last one observed at 43.7 cm^{-1} . These data give the following potential constants: $V_1 = 86 \pm 11$, $V_2 = 946 \pm 33$, $V_3 = 407 \pm 4$, $V_4 = 138 \pm 20$, and $V_6 = -14 \pm 7\text{ cm}^{-1}$ with a *trans* to *cis* barrier of $1297 \pm 26\text{ cm}^{-1}$.

Small Ring Molecules

Another type of large-amplitude anharmonic vibration is that of the ring puckering modes of small compounds. From the analysis of the frequencies for these ring-bending motions it is possible to obtain the potential surfaces for the interconversion of the different conformers. The equilibrium conformation of four-membered and unsaturated five-membered rings is determined by two major opposing forces. The first is the ring strain, which tends to keep the ring skeleton planar. Puckering the ring decreases the already strained angles, thereby increasing the angle strain. The second is the torsional forces. The torsional repulsions of adjacent groups are at a maximum for a planar ring since the groups are eclipsed; therefore, bending the ring out of the plane will reduce these repulsive forces. It is the delicate balance between these two large forces that determines the ground-state structure of the molecule.

A single substituent on the cyclobutane ring leads to conformational isomers and introduces asymmetry into the potential function for ring inversion. As the ring inverts, the substituent goes from the axial conformation to the equatorial, or vice versa. These two conformations will of course have different energies and the spectra can be interpreted using a potential function of the form

$$V(x) = ax^4 - bx^2 - cx^3$$

Figure 3 (a) Far-infrared transmission spectrum of chlorocyclopropane; (b) Raman spectrum of gaseous chlorocyclobutane.

where x is the coordinate of the ring inversion. The cubic term is added to the usual quartic-harmonic potential function because of the asymmetry.

The results for chlorocyclobutane will be used as an example of the utility of far-infrared spectra of the gas for the investigation of ring puckering motions. The far-infrared and Raman spectra of gaseous chlorocyclobutane in the region of the ring puckering fundamental are shown in **Figure 3**. From the far-infrared spectrum, this fundamental is observed as well-defined Q branches occurring at 157.55 , 149.29 , 139.81 , 130.12 and 128.08 cm^{-1} with additional, weaker Q branches at 116.46 , 115.69 ,

Figure 4 Potential function governing the conformational interchange for axial and equatorial chlorocyclobutane.

111.46 and 110.88 cm^{-1} . The first four pronounced Q branches appear to form a reasonable series and are assigned as the first four transitions of the ring puckering mode for the more stable equatorial conformer. From the Raman spectrum, the ring puckering fundamental is observed as a weak series of Q branches beginning at $\sim 158 \text{ cm}^{-1}$. Although the fundamental for the axial form can be assigned at 128 cm^{-1} in this Raman spectrum, the 128.08 cm^{-1} Q branch observed in the infrared spectrum is far more definitive.

With these assignments, the potential function governing ring inversion can be calculated with the aforementioned function. The function calculated using this assignment is shown in **Figure 4**. This potential is consistent with an energy difference between the equatorial and axial conformers of 449 cm^{-1} (1.28 kcal mol^{-1}) and a barrier to ring inversion of 827 cm^{-1} (2.36 kcal mol^{-1}). Although the uncertainty in the puckering angles determined at the minima is directly related to the uncertainty in the assumed reduced mass (198 amu), as well as the nature of the molecular motion involved, this potential gives puckering angles of 22° for the equatorial form and 17° for the axial conformer. From the *ab initio* calculations utilizing the 6-31G* basis set, the values for these angles are 25.1° and 20.3° , respectively, indicating that the difference in the two angles should be about 5° , which is the value obtained from the potential function.

In five-membered ring molecules, there are two low-frequency out-of-plane ring motions. These are usually qualitatively described as the ring-twisting (radial mode) and the ring-puckering (pseudorotational mode) motions. Initially, in order to handle the interpretation of the low-frequency far-infrared data, assumptions were made about the forms of these normal vibrations. If the five-

membered ring contains an endocyclic double bond, it has usually been assumed that there is no interaction between the 'high'-frequency ring-twisting mode, which falls around 400 cm^{-1} and the 'low'-frequency ring-puckering mode, which is near 100 cm^{-1} . Therefore, the two out-of-plane ring modes are handled as two one-dimensional problems with the anharmonic, low-frequency ring-puckering transitions interpreted in terms of a one-dimensional potential function of the form $V(x) = ax^4 \pm bx^2$. However, it has become increasingly clear that while a one-dimensional model of the ring-puckering motion yields reasonably good barrier height values, it does not allow for the interactions with other vibrational modes, which may often be significant.

Some of the most recent advances in the determination of potential surfaces governing ring inversions in four- and five-membered ring molecules have been in the development of two- and three-dimensional models. Such models then allow for the interaction of the ring puckering mode with other vibrational modes. These interactions have been shown to alter the puckering levels in the excited states of interacting motions and, if neglected, can result in poorly calculated barrier heights and misinterpretation of the far-infrared and Raman spectral features arising from the modes involved.

Skeletal Bending Nodes

The third type of low-frequency vibration is heavy-atom skeletal bending modes. Because the vibrations are of very low wavenumbers, there are frequently many excited states populated. Accordingly, the infrared contours in the gas phase can be very complex. In fact, many of these vibrations show a large number of excited states and the band contours are difficult to analyse because of the many vibrational-rotational transitions falling on top of each other. Attention to these types of vibrational modes has been fairly limited.

Gases, Liquids and Solids

Another type of absorption in the low-wavenumber range is due to the pure rotation of small molecules. The intensity of this type of absorption is frequently 10^4 times that of a low-wavenumber vibration, so very small amounts of HF, HCl, HBr, H_2O (see **Figure 1**) or other similar impurities result in relatively strong absorption from these molecules. This type of far-infrared absorption was studied extensively from the 1930s to the 1960s. The high-resolution infrared data obtained for these molecules made it possible to determine very accurate centrifugal distortional constants.

Only limited studies have been carried out on the far-infrared absorption of molecules in the liquid state,

which results in generalized absorption in the region of $30\text{--}80\text{ cm}^{-1}$. However, if the molecule contains hydrogen bonding, a significant amount of information can be obtained for the low-wavenumber vibrations resulting from the absorption of dimers of such molecules. These include the wavenumber for the $X \cdots H\text{--}Y$ stretching and bending.

Physicists have primarily carried out the spectroscopic study of solids in the far-infrared spectral region. A major exception to this generalization is the study of the lattice modes of molecular crystals. To account for the lattice (phonon) modes of solids, the Bravais space cell is used by molecular spectroscopists to obtain the irreducible representation for the lattice vibrations. The crystallographic unit cell may be identical with the Bravais cell or it may be larger by a multiple of 2, 3 or 4. The relationship between the Bravais cell and crystallographic cell can be obtained from the Hermann-Mauguin X-ray symbol that is used to designate the crystal symmetry. For all crystal structures designated by a symbol *P* (primitive), the crystallographic unit cell and the Bravais unit cell are identical. Crystal structures designated with capital letters A, B, C or I are double primitive and, therefore, the crystallographic unit cells contain two Bravais cells. Crystal structures designated with the letters R or F are triply and quadruply primitive, respectively, and the crystallographic unit cells contain three and four Bravais cells, respectively.

The potential energy of a crystal can be considered to be made up of the following terms: $V_{\text{Total}} = \sum_j V_j + \sum_i \sum_j V_{ij} + V_L + V_{Lj}$ where V_j is the potential due to the internal coordinates, V_{ij} is the potential due to the correlation field, V_L is the potential for the external degrees of freedom and V_{Lj} represents the potential due to the interaction of the internal modes with the lattice modes. Three symmetries must be considered when studying the vibrational spectrum of a crystal: the molecular symmetry, the site symmetry, and the factor group symmetry. The factor group is not a point group but it is isomorphous with the space group, which means there is a one-to-one correspondence between the two.

Oxamide (OCNH_2)₂ will be used as an example of the determination of the frequency of lattice modes. This molecule has molecular symmetry *trans* C_{2b} with space group *P1*. Oxamide has one molecule per unit cell so there are three acoustical translations, which are inactive, and three optical librations, which are only Raman active. The three lattice bands are very prominent features in the Raman spectrum and occur at 106 , 134 , 157 cm^{-1} (Figure 5) with corresponding bands at 100 , 137 , 156 cm^{-1} for the deuterated compound. An estimate of the range for the force constant of the librations can be calculated associating the highest torsional wavenumber with the largest moment of inertia and the lowest wavenumber with the smallest moment of inertia. The

Figure 5 Optical librational modes of oxamide.

widest possible range for the force constant is found to be 0.14 to $0.79\text{ mdyn \AA}^{-1}$. These values are relatively large for librational force constants and they reflect a high degree of hydrogen bonding for this compound.

For molecular crystals in which the molecules are nearly spherical there will frequently be a high-temperature crystal phase of which the site symmetry is higher than the molecular symmetry. These crystals are referred to as plastic crystals and they have unusual properties such as very high temperatures of melting and low anisotropic properties similar to those of liquids. The theory of lattice vibrations of orientationally disordered solids has been addressed, and the results indicate that such disorder should lead to a broadening of the vibrational bands and that all modes may be active in both the infrared and Raman spectra. Spectra of this type are referred to as density-of-states spectra, since the bands correspond to the flat points in the dispersion curve.

Ionic crystals are the other type of solid that has been studied extensively in the low-wavenumber spectral range. Of particular interests have been ferroelectrics, where one of the modes can shift from 150 cm^{-1} to nearly zero as the transition temperature is approached.

Fast Atom Bombardment Ionization in Mass Spectrometry

Magda Claeys and Jan Claereboudt, University of Antwerp (UIA), Belgium

This article is reproduced from the previous edition, volume 1, pp 505–512, © 1999, Elsevier Ltd.

Introduction

The mass spectrometry community uses 1981 as the starting point of fast atom bombardment (FAB) when Barber and co-workers published their first paper. The basis of FAB was laid down in the mid-1970s through pioneering research on static secondary ion mass spectrometry (SIMS) by Benninghoven. At the time of its discovery FAB meant a significant breakthrough in the analysis of polar biomolecules, such as peptides. Until then other ionization techniques such as field desorption, SIMS using ion beams and ^{252}Cf radiation, and laser desorption of ions from surfaces had been applied to the analysis of polar biomolecules with varying degrees of success and experimental difficulty. Since the development of FAB new powerful ionization techniques have emerged, namely matrix-assisted laser desorption ionization (MALDI) and electrospray ionization (ESI), which are routinely used nowadays and have greatly extended the applicability of mass spectrometry to polar biomolecules of high molecular mass ($M_r > 200\,000$). Despite the enormous successes of these last two ionization techniques, it is fair to state that FAB still enjoys an important place in bioanalytical laboratories involved in the analysis of molecules of medium polarity, including, for example, most natural products.

In FAB the sample ions are formed by bombardment of the sample in a liquid matrix with a high-energy beam of atoms (xenon or argon) or ions (caesium). The defining attribute of FAB is the use of a viscous liquid matrix to obtain long-lasting spectra and to 'soften' the sputtering process. The liquid matrix is able to provide continuous surface renewal so that intense primary beams may be used. The overall result is that secondary ion beams with a useful intensity for scanning mass spectrometers may be prolonged to periods of 20 min or more. Interestingly, the importance of the liquid matrix in FAB was not realized by Barber and co-workers when they discovered the technique. In their first article emphasis was laid on the use of fast atoms (argon) instead of ions as energetic bombarding particles and the term 'fast atom bombardment' was introduced to describe the new technique. However, similar spectra to those obtained using a fast neutral atom beam were achieved with better sensitivity using caesium or mercury ions as bombarding particles. The latter technique is known as 'liquid secondary-ion mass spectrometry' (LSIMS), but very often

and also in this review the acronym FAB is used to refer to LSIMS.

Instrumentation

The experimental set-up for FAB MS analysis is basically very simple and is illustrated in **Figure 1**. A beam of fast atoms is produced in a saddle field discharge source, called a 'FAB gun', by first ionizing an inert gas (Xe or Ar) to generate ions (Xe^+ or Ar^+) and accelerating these ions into an appropriate medium where the fast ions can capture an electron, thereby being converted from fast ions (having a kinetic energy due to acceleration) to fast atoms with energies as high as 10 keV. The beam of bombarding particles contains neutral atoms but also ions in various charge states. As illustrated in **Figure 1** the beam of bombarding particles is usually maintained at a large angle relative to the axis of the beam of secondary ions extracted by the ion optics. The intersection of the primary atom-ion beam and the secondary ion beam is at the focal point of the ion optics. The sample film is mounted on a clean metal tip of the FAB probe which is introduced into the mass spectrometer through a vacuum-lock assembly so that the sample surface rests at the focal point of the instrument.

The experimental set-up for LSIMS analysis is very similar; the only difference is the replacement of the fast atom gun by a caesium ion source which produces a

Figure 1 Experimental set-up for FAB.

focused beam of fast Cs^+ ions (up to 35 keV). The caesium ions are thermionically emitted from an alkali aluminosilicate solid maintained at high temperature (approximately 1000 °C). It is worth mentioning that caesium ion impact has largely replaced FAB in modern instruments. Advantages of the caesium ion source compared to a fast atom gun are that the energy distribution of the beam is narrow, beam focusing can be accomplished and the very low gas load introduced into the ion source.

Mechanism of Ion Formation

It should be noted that whilst most of the particle-induced desorption techniques are simple to perform, they are only partially understood in theory, i.e. there exists no clear understanding of the mechanisms involved in ion formation from organic molecules in the condensed phase. It is, however, striking that different desorption ionization (DI) techniques [including FAB and LSIMS but also plasma desorption (PD) and laser desorption (LD)] produce reasonably similar mass spectra from nonvolatile organic molecules. Similarities in the spectra produced with incident beams of keV atoms or ions, or MeV particles and photons, can only be explained by similar ion formation and ion dissociation processes occurring after the initially very different physical excitation process. A general mechanism for the DI process can be presented, at least schematically, by the following sequence of events:

It is evident that the primary processes involved in the energy deposition step are dependent on the type of physical excitation used, and some of the properties of the intermediate phase must depend on the nature of these primary processes. However, the final step, leading to the production of molecular ions and fragment ions, appears to be independent of the primary processes occurring in the condensed phase. It is reasonable to propose that in the processes of ion formation and stabilization, chemical reactions strongly influence the end-products. These reactions are believed to take place in the vibrationally excited, disturbed surface layer, known as the 'selvedge' region. Several models describing the mechanism of FAB are available in the literature. It can be stated that there are almost as many models as there are theoreticians studying the problem.

A Unified Model for Desorption Ionization

A comprehensive qualitative model for the DI process, as exemplified in FAB, LSIMS, PD and LD, has been proposed. The main features of this unified model are: (1) irrespective of its origin, the energy deposited at the sample surface is converted from its original form into vibrational energy; (2) desorption of intact molecules and preformed ions which can be described as a vibrational or thermal process (although no equilibrium is implied); (3) ion–molecule reactions (e.g. protonation, cationization and cluster ion formation) and EI occurring in the selvedge region; and (4) dissociation of energetic (metastable) ions well removed from the surface (i.e. in the vacuum region). A schematic illustration of this unified model is given in **Figure 2**.

In the unified model the processes of desorption and ionization are considered separately. Another characteristic of the model is that desorption is followed by chemical reactions of two types occurring in two distinct regions. First, in the selvedge region, fast atom/ion–molecule reactions and EI can take place. Second, in the free vacuum, unimolecular dissociations occur which are governed by the internal energy of the parent ion, the characteristic timescale of the instrument and the structures of the gas phase ions.

Ion Formation Mechanisms

The four major mechanisms for the formation of ions operating during FAB are: (1) direct desorption of preformed ions; (2) cationization (including protonation) and anionization in which a neutral analyte (M) is observed as adduct with a cation, i.e. $[\text{M} + \text{Cat}]^+$ or with an anion, i.e. $[\text{M} + \text{An}]^-$; (3) ion-beam induced processes leading to $[\text{M} - \text{H}]^+$ and $\text{M}^{+\bullet}$ ions; and (4) cluster ion formation. These four mechanisms cover most of the processes observed in FAB and largely describe the majority of ions detected in FAB spectra. Molecular ion-like species which are commonly encountered in FAB spectra are listed in **Table 1**.

Possible mechanisms for the formation of positive ions are given in **Table 2**; analogous mechanisms can be formulated for negative ions. That ion formation is the difficult, energetically demanding step in FAB is indicated by the observation that production of ions in the gas phase is much easier from samples that exist as preformed ions in the condensed phase than it is for neutral molecules. The mechanism by which preformed ions are converted into gaseous ions is conceptually the most straightforward: the molecular agitation generated by the bombarding particle, a process called 'sputtering', releases preformed ions into the gas phase. The types of compound that comprise preformed ions are inorganic salts, organic salts, and strong acids and bases. An artist's

conception of the violent activity at the surface of a matrix solution of the analyte is presented in **Figure 3**.

The next type of ion for which the formation can be easily rationalized is the [M + Cat]⁺ ions; [M + Na]⁺ is used as a typical example. However, attachment of other metal ions, especially alkali ions, also readily occurs if these ions are present in the sample. Na⁺ may be present in the sample as a salt impurity or it may be added deliberately by the analyst; it is a preformed ion which can attach to a neutral molecule (M) either in the gas phase or in the condensed phase. The [M + H]⁺ ions can be generated by a mechanism analogous to that proposed for [M + Na]⁺; in this case the preformed ion is the proton. Free protons are probably produced during particle bombardment at the impact site, or can be added deliberately in the sample in the form of a strong acid. Another mechanism for the formation of protonated molecules which has been considered is a disproportionation reaction, i.e. perturbation in a

Table 2 Possible ion formation mechanisms in FAB

Ions formed	Mechanism
Preformed ions e.g. Cat ⁺	Sputtering Cat ⁺ An [−] (cond.) → Cat ⁺ (gas) + An [−] (gas)
[M + Na] ⁺	Attachment of Na ⁺ in the gas phase Na ⁺ (cond.) → Na ⁺ (gas) M(cond.) → M(gas) M(gas) + Na ⁺ (gas) → [M + Na] ⁺ (gas) Attachment of Na ⁺ in the condensed phase followed by sputtering M(cond.) + Na ⁺ (cond.) → [M + Na] ⁺ (cond.) [M + Na] ⁺ (cond.) → [M + Na] ⁺ (gas)
[M + H] ⁺	Attachment of H ⁺ in the gas phase analogous to Na ⁺ attachment Attachment of H ⁺ in the condensed phase followed by sputtering, analogous to Na ⁺ attachment Disproportionation RO...HO (cond.) → ROH ₂ ⁺ (gas) + RO [−] (gas) H R

[M − H] ⁺	Fast atom–ion beam-induced reactions M(cond.) − H ₂ → [M − H ₂](cond.) [M − H ₂](cond.) + H ⁺ (cond.) → [M − H] ⁺ (cond.) [M − H] ⁺ (cond.) → [M − H] ⁺ (gas)

cond. = condensed phase.

Figure 3 Artist's conception of the violent activity taking place at the surface of a matrix solution during FAB.

hydrogen-bonded system caused by the bombarding particle can result in the sputtering of a $[M + H]^+$ ion and its complementary $[M - H]^-$ anion. True odd-electron molecular ions ($M^{+\bullet}$) are also formed, especially from compounds with low ionization potentials. $M^{+\bullet}$ ions are usually obtained for polyunsaturated molecules with conjugated systems, for example the fullerenes C_{60} and C_{70} . There is no firm evidence that $M^{+\bullet}$ ions are produced by direct EI. Current mechanistic studies focus on molecular hydrogen and hydrogen radical loss from protonated M which yield $[M - H]^+$ and $M^{+\bullet}$ ions respectively. $[M - H]^+$ and odd-electron $M^{+\bullet}$ ion formation in FAB was formerly attributed to gas-phase ionization-like processes but studies have demonstrated that fast atom-ion beam-induced processes should be considered.

The ion species of the types $[M + H]^+$, $[M - H]^-$ and $[M + Cat]^+$ are very useful for molecular mass determination, which is of key importance in the structure elucidation of natural products. For example, a literature survey in *The Journal of Natural Products* for the years 1996 and 1997 revealed that in 52% of the studies in which FAB was used, additional accurate mass measurement at high resolution was performed on molecular ion species to obtain the precise molecular composition.

Energy Deposition

FAB is generally regarded as a 'soft' ionization technique but the question may be asked: what is meant by 'soft'? Molecular ion-like species formed during FAB show little fragmentation, suggesting that they are formed with a low internal energy. Energy deposition during FAB has been addressed by several workers and it has been established that ions are formed with energies varying between 1 and 4 eV, revealing a maximum at 1 eV and a high-energy tail. The classification 'soft' should, therefore, be used with some caution.

Matrix Selection and Properties

The defining attribute of FAB is the use of a viscous liquid matrix. Consequently, many studies have been devoted to selection of suitable matrices in FAB. General matrix requirements concerning the solvent properties of the matrix are summarized as follows:

- (1) the samples must be soluble in the matrix;
- (2) only low vapour pressure solvents can be considered in the vacuum of the mass spectrometer;
- (3) the matrix must be electrically conductive to avoid charging of the surface layer;
- (4) ions from the matrix itself must not interfere with analyte ions in the FAB mass spectrum;
- (5) the matrix must be chemically inert.

Lists of useful matrices for FAB are available and their physical and chemical properties have been compiled. In the authors' laboratory where FAB is still routinely applied to the analysis of plant secondary metabolites such as saponins, flavonoid glycosides, fatty acid derivatives and small synthetic peptides ($M_r < 3000$), two matrices are mainly used: glycerol, in the analysis of polar hydrophilic compounds and *m*-nitrobenzylalcohol (*m*-NBA) for lipophilic compounds. When glycerol is selected the sample is first dissolved in a cosolvent, methanol or a methanol-water mixture, while in the case of *m*-NBA dichloromethane is employed as cosolvent to facilitate addition of the sample to the matrix. It is a misconception that FAB can only be applied to the analysis of polar analytes; lipophilic compounds such as fatty acids and their derivatives are well amenable to FAB analysis if a lipophilic matrix is selected. Other matrices that have often been employed in peptide analysis include thioglycerol and a eutectic mixture of dithiothreitol and dithioerythritol (3:1, w/w), known as 'magic bullet'. For negative ion FAB the basic matrices di- and triethanolamine have also been used.

Evaporation of the liquid matrix in the vacuum of the mass spectrometer has to be considered because it can result in significant changes of the physical state of the sample solution. The effect of matrix evaporation on secondary ion formation has been investigated for samples dissolved in glycerol with and without a cosolvent. Depending on the residence time of the sample solution in the vacuum, the bulk and surface concentration of the analyte in the matrix can become supersaturated, analyte molecules can precipitate, and as such the conditions for secondary ion formation can be altered. Fortunately, the solid layers formed by precipitation of analyte molecules at the surface of sample solutions can be removed by sputtering, thereby making the underlying layer amenable to FAB analysis. In other models where evaporation of the liquid matrix was not taken into account, replenishment of the surface layer has been rationalized by

diffusion of analyte molecules from the bulk to the surface layer. It is not likely that diffusion, which is not a rapid mechanism, is as important as previously thought to obtaining long-lasting analyte signals in FAB.

Sample Preparation for FAB Analysis

Impure samples of biological origin cannot be directly submitted to FAB analysis. Polar hydrophilic samples are usually isolated from a biological matrix containing alkali salts by chromatographic procedures employing buffers. When buffers are required for the isolation, preference is given to systems composed of volatile salts, acids and bases. Alkali salts can be eliminated from samples by resorting to simple desalting procedures based on the use of reversed phase cartridges. In the presence of Na^+ , for example, acidic compounds containing carboxylic or phenolic groups give rise to multiple sodiated molecular species (i.e. $[\text{M} + \text{Na}]^+$, $[\text{M} - \text{H} + 2\text{Na}]^+$ and $[\text{M} - 2\text{H} + 3\text{Na}]^+$) leading to decreased detection sensitivity. In order to improve the detection of peptides it is common practice to add a volatile strong acid such as trifluoroacetic acid to the analyte–matrix mixture whereby neutralization of the carboxylate part of the peptide zwitterionic structure results in an enhanced $[\text{M} + \text{H}]^+$ ion formation. Derivatization strategies to increase the solubility of the analyte in the liquid matrix or to convert the analyte into a salt form with better desorption properties may also be considered. Molecules containing labile groups which are prone to hydrolysis in FAB can be stabilized by using a Li^+ -containing matrix.

Continuous-Flow FAB

FAB is the basis for an effective coupling technique for liquid chromatography (LC), namely, continuous-flow FAB. A set-up for continuous-flow FAB is given in **Figure 4**. In this technique, a liquid flow of typically $5\text{--}10\ \mu\text{L min}^{-1}$ obtained by splitting the LC flow is

introduced into a heated FAB source via a narrow-bore fused silica capillary. The glycerol matrix is added to the LC effluent to a concentration of approximately 0.5% and subsequently the mixture is directed into the FAB source through a metallic frit. The liquid flow ensures that there is a continuous flow on the probe tip in which previously eluted sample is continuously removed from the area where sputtering occurs. In other designs there is no metal frit but then a cotton wick is used to disperse the solvent and to obtain stable operating conditions. In addition to coupling to LC, continuous-flow FAB has been shown to be a useful technique for the introduction of flow-injected samples and effluents of capillary electrophoresis and microdialysis.

Combination of FAB with Collision-Induced Dissociation and Tandem Mass Spectrometry

In order to obtain structural information on biomolecules it is common practice to use FAB in combination with collision-induced dissociation (CID) and tandem mass spectrometry. As discussed above FAB is a soft ionization technique producing mainly molecular ion-like species with a low internal energy. These species can be fragmented by CID during which the internal energy of the ions is increased. CID can be performed at low and high collision energies generally leading to different and complementary structural information. The FAB spectrum of compounds of biological origin is usually quite complex for several reasons: peaks due to the FAB matrix are always present but, in addition, impurities and salt forms of the molecular ions are often encountered making the interpretation of a FAB mass spectrum particularly difficult. Using CID and tandem mass spectrometry it is possible to obtain a spectrum of one well-defined molecular ion species allowing the corresponding fragment ions to be determined unambiguously. **Figure 5** illustrates first-order FAB spectra using glycerol

Figure 4 Experimental set-up for continuous-flow FAB.

Figure 5 First-order FAB spectra obtained using glycerol (G) as the liquid matrix for kaempferol-3-O-rutinoside, isolated from a medicinal plant, with (lower) and without (upper) subsequent desalting. Reprinted with permission from Li QM, Dillen L, and Claeys M (1992) Positive ion FAB analysis of flavonoid glycosides. as liquid matrix obtained for a flavonoid glycoside, kaempferol-3-O-rutinoside, which was isolated from the leaves of an African medicinal plant *Morinda morindoides*, with and without subsequent desalting. Without desalting several molecular ion species of kaempferol-3-O-

rutinoside are observed with low intensity, namely, $[M+H]^+$, $[M+Na]^+$, $[M-H+2Na]^+$ and $[M-2H+3Na]^+$. The presence of Na^+ in the sample is also evident from the matrix peaks including abundant sodiated species. Using desalting a sufficiently intense

$[M + H]^+$ signal could be obtained which was amenable to CID and tandem mass spectrometry. This methodology showed that the ions at m/z 287, 449 and 461 are fragment ions of the protonated molecule.

Selected Applications

A number of reviews and overviews are available in the literature. For comprehensive surveys of the literature the biennial reviews of mass spectrometry in the journal *Analytical Chemistry* can be consulted. As it is impossible to review all applications of FAB only selected applications will be mentioned here. FAB has been particularly useful for the analysis of peptides and proteins, providing molecular mass information for large peptides with an upper mass limit of approximately 24 000 Da. It can be stated that in the field of peptides and proteins FAB has now largely been overtaken, but not entirely replaced by, MALDI and ESI. Other biomolecules that have been successfully analysed using FAB are glycoconjugates, including glycopeptides, nucleotides, terpenoid and flavonoid glycosides, and complex lipids such as glycosphingolipids, gangliosides, phospholipids and steroids. The relatively frequent use of FAB compared to other soft ionization techniques (i.e. CI, ESI and MALDI) in natural product research can be attributed to the reliable molecular mass and composition that can be obtained which is of key importance in the structure characterization of unknown compounds. FAB has also been applied in areas that are not of direct biochemical interest, such as the analysis of dyestuffs, organometallics, quaternary ammonium salts, triphenyl phosphonium salts, surfactants and chiral complexes. With regard to this last application FAB has been found to be more suitable than ESI for studying enantioselective intermolecular interactions.

Fibre Optic Probes in Optical Spectroscopy, Clinical Applications

Introduction

In the clinical environment, optical techniques have been used for decades (microscope, colposcope, ophthalmoscope, endoscope, laparoscope). Integration of spectroscopic devices into existing procedures is an obvious task. Fibre optic cables provide a flexible solution for adequate optical interfacing between the optical and spectroscopic device and the sample to be interrogated *in situ*. Fibre optic probes can be inserted into cavities and tubular structures, put in contact with epithelial surfaces and also inserted into structures that can be punctuated by rigid devices such as needles. Fibre optic devices for optical spectroscopy can be manufactured as flexible catheters with an outer diameter not exceeding 0.5 mm. We will present in this article fibre optic solutions for fluorescence and both elastic and inelastic scattering detection. After describing the fibre optic interface, we will present probes for fluorescence spectroscopy followed by probes for reflectance measurements and side looking. Diffuser tips, refocusing and designs for Raman spectroscopy are discussed towards the end of the article.

The Fibre Optic Interface

A spectroscopic system incorporates a light source, an optical analyser with detector, and a light transport conduit which in many cases is made of fibre optic cables. A separate illumination and collection channel minimizes background signals produced in the illumination fibre (Figure 1a). The excitation or illumination light source is typically a laser or a filtered white light source such as xenon or mercury lamps. Dielectric bandpass filters (Omega Optical, Inc., Brattleboro, VT, USA), monochromators or double monochromators (ISA Edison, NJ, USA) can be used as filters according to the need for spectral purity. For fluorescence spectroscopy, xenon lamps (ORC, Azusa, CA, USA; Hamamatsu Corp. Bridgewater, NJ, USA) with more than 150 W power consumption need additional cold and hot mirrors to protect the optical parts. The coupling optics adapt the f-number of the light source to the numerical aperture of the fibre and guarantee optimal irradiance into the fibre. The probe transports the collected light to the spectroscopic system. New techniques such as holographic transmission gratings (Holospec, Kaiser Optical Systems

Figure 1 (a) A fibre optic spectroscopy system with separate illumination and collection path is based on an excitation source, which is a laser or a white light source (reflectometry) or a monochromator filtered arc lamp (fluorescence). Optics couple the excitation light into the flexible probe. A probe collects the emitted light. Coupling optics adapt the numerical aperture of the probe to the spectrograph or filter system. An optical detector (charge coupled device (CCD), photodiode array, photomultiplier tube) is read out and digitized. (b) A fibre optic spectroscopy system with a probe that incorporates one optical fibre needs a dichroic beam splitter and well-aligned optics to separate excitation and fluorescence light. Reproduced with permission of Optical Society of America Inc. from Greek LS, Schulze HG, Blades MW, Haynes CA, Klein K-F, and Turner RFB (1998) Fiber-optic probes with improved excitation and collection efficiency for deep-UV Raman and resonance Raman spectroscopy. *Applied Optics* 37(1).

Inc., Ann Arbor, MI, USA) and back-illuminated thinned CCDs with high quantum efficiencies (Princeton Instruments, Inc., Trenton, NJ, USA) allow short integration times and sufficient spectral and spatial resolution. Additional filter stages reduce the influence of stray light in the spectrograph. Most fluorescence applications require longpass (Schott Glass Technologies Inc., Duryea, PA, USA) and Raman spectroscopy devices notch filters (Holographic notch filters, Kaiser Optical System Inc.).

To achieve smallest possible probe diameters, single fibre solutions are used in combination with a dichroic beam splitter and with well-aligned coupling optics (Figure 1b). Single fibre solutions are limited by the difficulty of reducing back-scattered excitation light and the suppression of parasitic light induced by the illumination path of the probe.

Fibre Optic Cables

An optical fibre for spectroscopy consists of a silica core, a doped cladding and a protective jacket. Light is transmitted based on the principle of total internal reflection. Half of the maximal angle (α) a fibre can accept light is characterized by the numerical aperture (NA), which is defined by the difference in the refractive indices (n) of the core and cladding (Figure 2):

$$NA = n_{\text{media}} \sin \alpha = \sqrt{n_{\text{core}}^2 - n_{\text{cladding}}^2}$$

Improvements in the preform manufacturing (Heraeus Amersil Inc., Duluth, GA, USA) allow transmittance from 200 nm (solarization-resistant-UV grade fibre, Polymicro Technologies, Inc., Phoenix, AZ, USA) up to 2500 nm (low-OH fibre, Fiberguide Industries, Inc., Stirling, NJ, USA; Ceramoptec, Bonn, Germany). This opens the application of fibre optic probes to UV resonance Raman (UVR) and IR Raman spectroscopy. Due

Figure 2 A fibre optic cable for spectroscopy consists of a core material (quartz) and a cladding with a lower refractive index (doped quartz) and a rugged supportive jacket. Light is transported by total internal reflection.

to bending of the fibre and scattering centres in the fibre, light may exit into the cladding and hit the jacket. Most plastic claddings like Nylon and Tefzel[®] (DuPont, Wilmington, NJ, USA) produce significant autofluorescence when irradiated with UV light. Polyimide (Thermocoat, Fiberguide Industries Inc.) and metallic coated fibres (gold, aluminium) exhibit minimal fluorescence. Colour centres may be produced during UV radiation in quartz and the fibres fluoresce in a broad band at 450 and 650 nm. This process is reversible but depends on the pulse repetition rate and the pulse energy. It is further known that silica produces Raman intrinsic signals at NIR excitation, which interfere with *in vivo* Raman spectroscopy such that the dynamic range of the detector becomes critical.

Fluorescence Probes

A growing number of clinical studies have demonstrated that fluorescence spectroscopy can be used to distinguish normal and abnormal human tissues *in vivo* in the skin, head and neck, genito-urinary tract, gastrointestinal tract, breast and brain. It is well known that fluorescence intensity and lineshape are a function of both the excitation and emission wavelength in samples containing multiple chromophores, such as human tissue. Major fluorescence contributors are structural proteins, NADH, FAD, tryptophan and porphyrins.

Single Pixel Measurements

The classic fibre optic probe to measure fluorescence consists of at least one excitation and one collection fibre (Figure 3a). A quartz shield placed at the distal end of the fibres allows the illuminated and probed areas to overlap. The fraction of overlapping increases with an enlargement of the numerical aperture of the fibres and the thickness of the shield. A larger shield depth requires a larger diameter shield. The collection efficiency β_t for an isotropic fluorescence source can be described as:

$$\beta_t = \frac{\beta_0}{(z + \text{shield}_t)^2}$$

where z is the position along the optical axis of the probe and β_0 a constant which includes the detector efficiency. Previous studies performed in arterial tissue have demonstrated empirically that tissue does not emit isotropically, as a result of high forward scattering. For arterial specimens, tissue fluorescence power decreases with the detector-sample separation distance, R , as $1/R^n$, where $n = 1.1$. A typical thickness of the shield is 1.7–6.4 mm. However, scattered fluorescence could also be detected without a shield. A typical probe consists of excitation fibres, collection fibres, carbon filled epoxy and

Figure 3 (a) The classic fibre optic probe for fluorescence spectroscopy is based on two or more fibres. Hexagonal packing is a dense arrangement and allows the selection of multiple fibres for different excitation sources and collection channels. A quartz shield permits the overlap of excitation and collection areas. The parts are: (a) excitation fibres; (b) collection fibres; (c) tubing; (d) carbon filled glue; (e) sleeve; (f) shield. (b) A typical fluorescence probe for single point sampling; (a) excitation fibres; (b) collection fibres; (c) sleeve. (c) A hexagonal fibre bundle with a melted and compressed arrangement allows excellent illumination and interrogation overlap. Reproduced by permission of Innova Quartz Inc.

tubing. A rigid type uses metallic tubing, a flexible type uses shrinking tubing (Zeus Industrial Products Inc., Orangeburg, SC, USA). The shield and sleeve are detachable to allow disinfection of the probe. A probe based on seven 200 μm fibres has a diameter of at least 1.5 mm. The probe with an outer diameter of 4 mm presented in **Figure 3b** has been successfully used by Ramanujam and the authors in studies with more than 100 patients.

InnovaQuartz (InnovaQuartz, Phoenix, AZ, USA) has successfully manufactured fibre optic tips, using CO_2 laser micro machining (**Figure 3c**). Melting and compressing the fibres eliminates the dead space between them. An increase of power density and almost complete overlap between illumination and collection areas has

been reported. However, this technique is limited to fibre bundles with a few fibres only.

Multi-Pixel Measurements

Pitris, Agrawal and co-workers have successfully adopted the principle of single pixel fluorescence measurements into a design of 31 simultaneous measurement locations (**Figure 4a**, and **4b**) without sacrificing spectral resolution. Modern imaging spectrographs for fluorescence applications (Instruments SA, Edison, NJ, USA; Chromex, Albuquerque, NM, USA) allow the simultaneous spectral dispersion of up to 30 input channels with minimal cross talk. Aberration corrected spectrographs

Figure 4 (a) A multi-pixel fibre optic design based on the design of **Figure 3a**. At each sample spot one collection fibre is surrounded by one to six illumination fibres. Signal tunneling from in between sample spots can be influenced by the separation of the collection and emission fibres and the shield thickness. (b) A typical fluorescence probe for simultaneous multi-pixel measurements. Black shrinking tubing holds the quartz shield. Emission and collection fibre pairs are arranged hexagonally.

project the input slit onto CCD devices with a focal plane size of 30×12 mm (TRIAX, Spectrum One MCR, Instruments SA). Spot scanning and imaging devices increase the spatial resolution further at the cost of spectral resolution. **Figure 4a** illustrates the hexagonal arrangement of the fibre pairs. Adding excitation fibres can increase the illumination intensity. With lamp-based excitation sources the focal spot size at the coupling site is determined by the arc size, which is typically in the order of 0.5–3 mm. A 300 W xenon lamp with parabolic reflector (Compact Illuminator 6000CI, ORC) produces a spot diameter of approximately 7 mm after a lens with a focal length of 50 mm. According to the formula for hexagonal packing:

$$n_{\text{fiber}} = 1 + \sum_{k=0}^m 6k$$

where m is the total number of rings, 547 fibres with a core diameter of $200 \mu\text{m}$ can be successfully located in this spot which would lead up to 17 excitation fibres per fluorescence collection fibre. **Figure 4b** shows a multi-pixel probe, which is used by the authors for fluorescence distribution studies. The outer diameter is 25 mm and the shield thickness 6.4 mm.

Separation of Illumination and Detection Spot

Keijzer and co-workers described scattering of fluorescence outside the illumination spot experimentally and theoretically (**Figure 5**) for arterial tissue. β and α absorption bands of oxygenated haemoglobin alter the fluorescence spectra. This effect is evident when the illumination and collection spot do not overlap so the spacing of the collection spots and the shield thickness have to be chosen carefully. In order to enhance the absorption influence on fluorescence spectra, the excitation and collection fibres need to be further separated (**Figure 4a**).

Reflectance Probes

The multiply scattered light that escapes the sampling volume is called reflectance. The transport mean free path length of a photon is defined as:

$$\text{mfp}' = \frac{1}{(\mu_a + \mu_s')}$$

where μ_a is the absorption coefficient and μ_s' is the reduced scattering coefficient which is the isotropic

Figure 5 Cross talk. Fluorescence generated in a 1 mm spot area is detectable from an outside area. It spreads by scattering processes and will be reshaped by absorption processes. Monte Carlo simulations and measured data show that haemoglobin absorption in tissue affects emission intensities at 580 nm more than at 600 nm. Adapted with permission from Keijser M, Richards-Kortum RR, Jacques SL, and Feld MS (1989) Fluorescence spectroscopy of turbid media: Autofluorescence of the human aorta. *Applied Optics* 28(20): 4286–4292.

Figure 6 (a) A fibre optic probe for reflectometry. The light scattered from a single excitation fibre is detected by a linear array of collection fibres. Tilting the excitation fibre shifts the profile along the surface by an amount that is determined by the sample's optical properties. (b) A fibre optic probe with a circular fibre arrangement for reflectometry. A 2 cm probe head consist of a central calibration fibre, an excitation fibre and non-equally spaced fibres. Neutral density (ND) filters adapt the light intensity in a transfer array to a smaller dynamic range.

equivalent of the anisotropic scattering medium:

$$\mu'_s = \mu_s(1 - g)$$

where g is the average cosine of the scattering angle and μ_s the scattering coefficient. The optical properties μ_s , μ_a and g depend on the chemical and architectural composition of the sample. The chemical composition of tissue depends on the blood supply, the metabolic state and the tissue type. The architecture of the sample is reflected in the shape and size distribution of the scattering particles. All these characteristics vary spatially and are wavelength dependent. Several studies have suggested that differences in the optical properties, assessed using diffuse reflectance spectroscopy, can be used

to discriminate normal and abnormal human tissues *in vivo* in the urinary bladder, pancreas and the skin.

The goal of fibre optic probes for reflectometry is to measure the reflectance distribution and to derive the optical properties by fitting the data to analytic expressions based on diffusion theory or iterative algorithms based on Monte Carlo modelling. Therefore fibre optic probes consist of a single excitation source and several spatially distributed collection fibres (**Figure 6a** and **6b**). A probe with a linear alignment constructed by Wang and co-workers places the detection fibres over a range of ± 1 to 10 mfp' (**Figure 6a**). Nichols and co-workers use a circular arrangement with a similar range (**Figure 6b**). This results in probes with a diameter of approximately 2 cm and an assumption that the optical

properties do not vary over this range. However the optical properties on currently investigated target areas (e.g. cervix, ovaries, oral cavity) vary over orders of millimetres (lesion size) and their size is similar to the diameter of the proposed probes. Therefore an accurate measurement of optical properties from small, pre-malignant lesions is difficult.

Wang and co-workers modified their linear probe design with an oblique incident source fibre and measured the shift of the reflectance profile. This removes the necessity of measuring in absolute units. The circular fibre arrangement of Nichols and others allows a simple calibration of the system by placing a source fibre in the centre of all fibres (**Figure 6b**). Measuring the spectrally resolved reflectance of all fibres simultaneously requires a dynamic range of 4 orders of magnitude. Neutral density filters or other techniques reduce the dynamic range required.

Combined Probes for Fluorescence and Reflectance Spectroscopy

It is well known that the absorption and scattering properties of tissues *in vivo* affect both the intensity and the lineshape of measured fluorescence spectra. Furthermore, measuring both fluorescence and diffuse reflectance spectra may provide additional information of diagnostic value.

A probe that combines the measurement of fluorescence and optical properties was described by Durkin. Scattered light is collected with a white light 'transmission' measurement which travels through the same tissue volume that was excited for fluorescence measurements.

The probe, illustrated in **Figure 7**, consists of a total of 21 optical fibres (200 μm diameter, $\text{NA} = 0.2$) arranged in concentric bundles. The centre bundle contains seven fluorescence excitation fibres and twelve fluorescence collection fibres. At the distal end of the probe the fibres which excite and collect fluorescence are sealed with a quartz shield. This shield is placed in contact with the sample surface, and ensures that the area from which fluorescence is collected is the same as that directly illuminated. The reflectance fibres are flush with the tip of the central shield. Similar attempts have been previously described in the literature.

Side-Looking Probes and Their Application

Oblique polishing of individual fibres deflects the output of the fibre with respect to the fibre axis (**Figure 8a**). If the critical angle for total internal reflection is reached, the light will leave the fibre through the cylindrical side. The shape of the fibre wall focuses the beam in an angular direction resulting in an elliptical focal spot close to

Figure 7 A fibre optic probe that combines fluorescence and reflectance measurements. White light tunnels through the fluoresced sample volume; (a) excitation fibres; (b) fluorescence collection fibres; (c) carbon filled glue; (d) outer tubing; (e) quartz shield; (f) white light illumination; (g) reflectance collection.

the fibre surface. The critical angles for the silica–water and the silica–air interface are 66° and 43.3° respectively. In order to permit the light to leave the fibre sideways at the tip, the jacket needs to be stripped. Depending on the jacket material, it can be dissolved in acid, mechanically abraded or burned away with a lighter.

Illumination analysis (ASAP, Breault Research Organization Inc., Tucson, AZ, USA) shows maximal irradiance increase at a polishing angle of 40° for water and air as surrounding media. The focal position is at a distance of 1.3 times the cladding radius positioned away from the side of the fibre in air and 3.17 times the radius in water. The increase of irradiance is 1.6 in water and 2.36 in air (**Figure 8b**).

Many probe designs are based on the oblique polishing of fibres (InnovaQuartz; Gaser, Visonex Inc., Warner Robins, GA, USA). **Figure 8c** (left) shows a design where the sampling volume of a single excitation fibre overlaps with concentrically arranged fibres. To construct the tip, which will be used in fluids, the fibre bundle is glued together. After its conical polishing, the middle fibre is polished flat. In order to measure on a sample surface the tip can also be enclosed at the distal end with a quartz or sapphire window (**Figure 8c** right).

Enclosing the oblique polished fibre in a glass capillary tube allows the production of minimal diameter deflecting probes. These off the shelf products (MicroQuartz) are used for vaporization and coagulation of tissue, but they could also be used for spectroscopic applications with a single or double fibre system (**Figure 8d**).

Figure 8 (a) Oblique polished fibres deflect the output beam or focus it at the sidewall of the fibre. (b) Illumination analysis with a uniform spatial and angular light distribution inside the fibre show a focusing in air and aqueous surrounding media. Irradiance increases to a factor of 2 in the focal spot. (c) Two probe designs for the interrogation of liquids (left) and surfaces (right). A central fibre illuminates the sampling volume or the surface. Six surrounding fibres collect the emitted light. Collection and emission are interchangeable. Housing with a thin shield (quartz, sapphire) permits a constant sampling distance for surface measurements. (d) Oblique polished fibres are enclosed in quartz capillary tubing for minimal diameter side-looking probes. A two-fibre arrangement for separate illumination and collection paths can also be manufactured (InnovaQuartz). (e) A circular arrangement of oblique polished fibres allows the fabrication of a ring probe with separate illumination and excitation channels.

If separate illumination and collection fibres are needed, their alignment will be a tedious task. An example of separate illumination and collection fibres is shown in **Figure 8e**. In order to produce a ring probe, fibre pairs are mounted in a cylindrical tube with grooves. A simultaneous investigation of sites along the circumference of the probe is possible (ring probe). The fibre pairs need to be aligned so that the illumination and collection spot overlap. Shrinking tubing or elastic bands could assist in this task.

Diffuser Tips

With the medical approval of photosensitive drugs such as Photofrin[®] (QLT PhotoTherapeutics Inc., Vancouver, BC, Canada) by the US Food and Drug Administration and the plans for clinical trials with Texaphyrin, the market for probes with a homogeneous illumination of large areas in canals and on surfaces is growing (OPTIGUIDE[®] QLT Photo Therapeutics LIGHT-STIC[®] Rare Earth Medical, Yarmouth, MA, USA). Diffusely scattering volumes mounted at the end of fibres or fibre bundles distribute light over large areas. Besides therapeutic applications such as photodynamic therapy (Lambda Plus Photodynamic Laser, Coherent Palo Alto, CA, USA) and coagulation these diffuse light delivery systems can also be used for illumination of spectral measurements.

Scattering particles are titanium (TiO₂) or aluminium oxide (Al₂O₃) which are embedded in a transparent matrix such as optical glue (Epo-tek 305, Epoxy Technology, Inc., Billerica, MA, USA). Flexible containment is produced with micro tubing based on fluoropolymers (PTFE, FEP from Zeus, Orangeburg, SC, USA). Rigid tips are based on ceramic or materials similar to Spectralon (Labsphere, North Sutton, NH, USA). Using UV radiation for fluorescence excitation the autofluorescence and transmission of these materials is of importance. FEP tubing (0.3 mm wall thickness) shows good transmission from 250 nm up to 2 μ m (40% at 250 nm, VIS 80–90%) while autofluorescence is at least an order of magnitude lower than tissue fluorescence. Al₂O₃ does not fluoresce in the UV-visible range.

Lightsticks[®] show uniform light distribution along the optical axis: a reflector mounted at the end of the cylindrical scattering volume reflects light that would otherwise leave the probe backwards. The length of the probe determines the concentration of scatterers (**Figure 9a** and **9b**).

A reflective foil (aluminium, gold) placed around a diffuser tip restricts the angular illumination. The foil is attached with a light wall shrinking tubing (**Figure 9c**) and the result of a 180° illumination is illustrated in **Figure 9d**. Oblique polished fibres probe the light emitted by the

sample area. The jacket of the fibres needs to be removed in order to pass the illumination light. A design based on this principle was proposed by the authors for fluorescence measurements in the endocervical canal.

A Sapphire Tip-Based Ring Probe

Sampling along the circumference of the probe is useful to identify the angular position of obstructions in tubes (e.g. arteriosclerosis). A probe initially designed for radial ablation and simultaneous spectroscopic analysis is illustrated in **Figure 10a**. The fibres are glued onto a metallic ring (outer diameter 2.4 mm, inner diameter 2.05 mm). A hollow plug attaches internal flexible tubing for flushing and a guide wire. A custom-made sapphire prism (Swiss Jewel, Tenero, Switzerland) is attached to the plug. The output of the fibres (NA = 0.22) is totally deflected at the back surface of the prism. NA is the numerical aperture, whose value is sine of half the angle $\times$ index of refraction. An outer flexible silicone tube isolates the tip from the liquid environment. Two different outer diameters were realized: 1.4 and 2.8 mm. **Figure 10b** shows the individual parts partially assembled. In the upper figure the outer tubing is not completely mounted. For spectroscopic measurements, smaller 100 μ m fibres were integrated in between the ablation fibres (lower figure). The sealing of such a tip is a tedious task since only small amounts of glue can be used.

Similar tips can be produced with vee-, ring-, orifice-, cup- and chisel jewels (Swiss Jewel, Tenero, Switzerland; Sapphire Engineering Inc., Pocasset, MA, USA; SWIP, Biel, Switzerland).

Refocusing

In order to increase the irradiance or the view of field on the sample area while keeping the distance to the fibres, applications may require converging the excitation beam. Focusing the beam reduces the measurement spot size. If the specimen is put outside the focus, illumination intensities drop while larger areas are illuminated.

Spherical Fibre Tips

Melting the end of the fibre shapes the exit surface of optical fibres. An almost spherical surface will be created by the surface tension of liquid quartz. Its form is determined by the volume of melted quartz, which is equivalent to the amount of absorbed energy. Several techniques have been used to achieve this deformation: micro furnace, Bunsen micro-burner, electrical arc and a CO₂ laser beam.

Figure 9 (a) A diffuser mounted as a tip on a fibre bundle allows uniform illumination along the probe axis (Lightstick[®], Rare Earth Medical, Inc.). A (metallic) reflector (1) at the diffuser end and the local concentration of scattering particles (3) determine the intensity profile. Tubing (2) made of fluoropolymers has a high transmission and good heat resistance. (b) A Lightstick[®] with a length of 2 cm and a reflector allows axial illumination with a 180° field of view. (Courtesy of Rare Earth Medical, Inc., West Yarmouth, MA, USA). (c) This line-sampling probe is based on a combination of a diffuser illuminator (2) and oblique polished fibres (3). With the jacket removed from the collection fibre, the light emitted by the diffuser passes and interacts with tubular surfaces. A metallic foil (1) restricts the illumination to a reduced angle.

Figure 10 (a) A sapphire prism deflects the output of a fibre ring into a radial direction. The probe consists of a plug holding the prism and inner tubing. Fibres are glued into a metallic ring. Outer tubing and glue seal the fibre tip. (b) In the upper picture the sapphire prism and the fibres are partially assembled. The lower figure shows the arrangement of illumination and smaller collection fibres in a metallic ring.

The smallest possible surface curvature is a hemisphere and theoretical results are shown in water and air. The beam exiting a hemispherical fibre tip in air and water is shown in **Figure 11a**. Because the refractive index of silica is 1.46, the focusing power is limited in aqueous media. **Figure 11b** illustrates the focusing of a fibre with a 200 µm core diameter and an NA of 0.22 in air and water. The beam in water is reduced to a quasi-parallel beam. A local concentration of rays can be found at a distance 3 times the distal radius of curvature from the vertex. The maximal irradiance was found to be 3 times the irradiance within the fibre.

Ball Lenses

Spherical ball lenses have been used as collimators in fibre optic connectors. Sapphire spheres with a high refractive power are industrially produced in a wide range of diameters (Sandoz SA, Cugy, Switzerland; Rubis Precis, Charquemont, France). Light emitted from a fibre can be focused with this lens type onto the sample site (**Figure 12a**). Rol found a maximal performance when the ratio of the back surface distance to the fibre and the radius of the sphere is between 1.8 and 2.8 in water and air. Illumination analysis (ASAP) shows a maximal

Figure 11 (a) Hemispherically shaped ends of fibres focus the output beam in air and collimate it in water. Adapted with permission from Rol P and Niederer P (1991) High-power laser transmission through optical fibres: Applications to ophthalmology. In: Wolbarsht ML (ed.) *Laser Applications in Medicine and Biology*, vol. 5, pp. 141–198. New York: Plenum. (b) Maximal irradiance is found at a distance of 3 times the fibre radius in water for quartz fibres with an NA of 0.2. The irradiance increases by a factor of 3.

increase of the irradiance by a factor of 4.8 in water and 5.7 in air (**Figure 12b**). If the fibre diameter is increased, spherical aberrations will become important.

A fibre optic probe (**Figure 12a**) with a 200 μm core diameter fibre and a sphere with a radius of 0.4 mm will not exceed an outer diameter of 0.9 mm. The sphere and fibre can be held in a cylinder with a conic inner shape. For side-looking applications the same principle is used with a half sphere. If the plane is inclined by 45° and the step in the refractive index is equivalent to sapphire–air, the beam will be deflected with total internal reflection at the interface and leave the probe at 90° with respect to the probe axis. A micro quartz tube encloses the half sphere and provides air as the refractive medium.

Spherical and Parabolic Reflectors

Mirrors can concentrate light. The complex refractive index of dielectrics defines the absorption coefficient and the normal incidence reflectance of a mirror:

$$\hat{n} = n + i\kappa$$

$$\mu_a = \frac{4\pi\kappa}{\lambda}$$

$$R_{\perp} = \frac{(n-1)^2 + \kappa^2}{(n+1)^2 + \kappa^2}$$

where $\hat{n}$ is the complex index of refraction, n is the index of refraction, κ is the extinction coefficient, λ is the wavelength and $R_{\perp}$ is the normal incidence reflection.

For side-looking applications, parabolic or spherically polished mirrors focus the output of several fibres onto the same area (**Figure 13a**). Best performance is shown by a parabolic surface. The manufacture of such mirrors requires a high-precision numerically controlled lathe. Surfaces with optical quality can be manufactured with single-point-diamond-cutting machines.

An example of a probe illuminating a ring is shown in **Figure 13b**. A fibre ring bundle is glued into a metallic ring. A plug with the optimized polished surface is centred into this ring and deflects the axial fibre output in a radial direction. A quartz tube shields the reflective surface. Illumination simulations (ASAP) show that the output of 5 fibres overlap (**Figure 13c**). The rotationally symmetric design spreads the light from the fibres in a quasi-elliptical spot around the circumference. The inner and outer concentric rings of fibres overlap at the cylindrical sample surface. This design confines the sampling volume close to the probe surface because outside the focal spot the light diverges rapidly.

Probes for NIR and UVR Raman Spectroscopy

Near-infrared Raman scattering can be used as a tool to perform *in situ* histochemical analysis. In biological applications approximately 10^{-10} of the incident light is Raman scattered and the Raman signal is normally 6 orders of magnitude weaker than typical fluorescence

Figure 12 (a) Ball lenses image the output of a fibre and focus it. A deflecting surface is integrated with a half sphere. On this surface light is internally reflected when using a sapphire–air boundary. The deflecting probe is housed in a quartz tubing, while the axial probe will also focus in aqueous media surrounding the exit surface of the sphere. Adapted with permission from Rol P, Utzinger U, Beck D, and Niederer PF (1995) Fiber beam shaping and ophthalmic applications. *SPIE Lasers in Ophthalmology II* 2330: 56–62. (b) Illumination analysis demonstrates a fivefold increase of irradiance in the focal spot. (b) Illumination analysis demonstrates a fivefold increase of irradiance in the focal spot.

signals. The amount of light that can be delivered to the sample area is limited due to overheating and American National Standard for Safe Use of Lasers (ANSI) safety standards. The design of a fibre optic probe is therefore driven by the need for maximal light collection. Additional background signal originating from the laser source, the fibres and all optical components is crucial in filling the dynamic range of the detector and producing

additional Raman signals. These signals must be reduced with filters for sensitive *in vivo* measurements.

A design developed by Myrick and Angel (**Figure 14a**) is based on GRIN lenses (NSG, Tokyo, Japan). Filters are placed in the excitation and emission paths and allow remote analysis with fibre optic cables. The light source is bandpassed to eliminate signals produced in the fibres and a longpass filter reduces Fresnel

Figure 13 (a) Parabolic or spherical mirrors focus and deflect the fibre output. Rotationally symmetric mirrors with optical surface quality can be manufactured with numerically controlled diamond turning machines. (b) A fibre optic ring probe with a parabolic reflector. As in **Figure 10a** the plug is mounted into the ring of fibres and flexible tubing. A short piece of quartz tube isolates the mirror from the probe environment. (c) Illumination analysis of the output from 5 fibres shows a good overlap of the fibres placed closer and further out from the axis. In the circumferential direction the measurement spot spreads out.

Figure 14 (a) A fibre optic probe for Raman spectroscopy based on separate illumination and collection fibres. The output of the fibres is collimated and filtered and then projected onto the same area on the sample. Bandpass filters are used for the excitation fibres and longpass filters for the collection fibres. GRIN lenses are assembled into the probe in order to maintain small diameters. (b) A fibre optic probe based on the design in **Figure 8c**. In-line filters are mounted into spring loaded SMA connectors. The fibre length between the tip and the filters is kept short. Adapted with permission from Nave S, O'Rourke P, and Toole W (1995) Sampling probes enhance remote chemical analysis. *Laser Focus World* December: 83–88. (c) A CPC Raman collection system consists of: (1) NIR diode laser; (2) collimating lens; (3) reflective mirror; (4) dichroic mirror; (5) focusing lens; (6) parabolic concentrator; (7) field lenses to prevent vignetting; (8) a focusing lens to couple the Raman signal into the collection fibre bundle (9) and a high efficiency spectrograph with a liquid nitrogen cooled CCD (10). (d) Raman probe. The excitation light is transported through a single fibre (5) and imaged with a biconvex lens (6) through a dielectric bandpass filter via a mirror (7) onto the sample area. The inelastic scattered light is collected behind a quartz window (4) and imaged by lenses (4) and (2) through an aperture stop and a holographic notch filter onto a flexible fibre bundle (1). (e) The UVRR spectroscopy probe incorporates a smaller diameter solarization-resistant-UV-grade quartz fibre for excitation and an oblique polished fibre to collect scattered light close to the excitation fibre. Reproduced with permission from Schulze HG, Bludes MW, Haynes CA, Klein KF, and Turner RFB (1998) Fiber-optic probes with improved excitation and collection efficiency for deep UV Raman and resonance spectroscopy. *Applied Optics* 37(1): 170–180.

and elastic scattered light that enters into the collection fibres.

A similar approach is shown in **Figure 14b**. A probe developed by Savannah River Technology Center (Aiken, USA) consists of dielectric filters placed between fibres which are held with spring-loaded SMA connectors. Six collection fibres are arranged around an excitation fibre. They are arranged as shown in **Figure 8c**. A sapphire window isolates the probe from the surrounding environment.

Berger, Tanaka, and other workers have developed a novel design for improved signal collection to allow spectral acquisition in a short time. A compound parabolic concentrator (CPC) is used at the distal end of the probe. They produced a hollow shell, based on a mandrel, electrolytically. The mandrel followed an optimized parabolic form, which was cut with a numerically controlled lathe. Small CPC dimensions with an input aperture of 0.57 mm, exit aperture of 2.1 mm and length of 4.1 mm were achieved (**Figure 14c**). The probe design with the CPC improved the collection efficiency sixfold. The system incorporates a 500 mW tunable 830 nm diode laser, which is coupled with a mirror and a dichroic beam splitter onto the sample site. Inelastic scattered light exciting the CPC is further collimated with the first lens and filtered by the dichroic mirror and additional filters. Field lenses prevent vignetting of the signal. The last lens images the output onto 200 100 μm fibres, which illuminate a $f/1.8$ spectrograph. The signal is detected with a back illuminated, liquid nitrogen cooled charge coupled device (CCD). Spectral resolution is 13 cm^{-1} .

Mahadevan-Jansen and the authors have successfully measured Raman spectra on the cervix with a fibre optic probe in less than 3 minutes (**Figure 14d**). A diode laser is coupled into a single 200 μm fibre. A small diameter dielectric filter (3–4 mm) rejects out-of-band light (optical density (OD)5) and a gold mirror deflects the focused beam onto the specimen site. The beam has to pass a quartz window, which is a part of the housing. Scattered light from the same spot area is imaged with biconvex lenses on a fibre bundle. Elastic scattered and Fresnel reflected light are rejected with a beam aperture stop and a holographic notch filter (OD6). The optics in the detection arm are 8 mm in diameter and the whole probe diameter is less than 2 cm. A similar spectroscopic detection system is used as described in **Figure 14c**. The spectrograph with the holographic transmission grating (Holospec, Kaiseroptics) and the deep depletion, back illuminated, liquid nitrogen cooled CCD allow optimal system performance (Princeton Instruments).

All the Raman probes described above include imaging optics to enhance the collection efficiency. This makes it difficult to correct the spectral throughput of the system with standardized radiators such as the tungsten filament lamp. The lamp needs to be imaged onto the

location of the measurement site and the NA of the probe has to be filled with the light source. The intensity of the source needs to be reduced by orders of magnitude in order to prevent detector saturation.

The scattering cross-section for Raman events can be increased dramatically if excitation is effected using photons in resonance with the electronic transitions of the chromophore involved in the fibrillation. For many biologically relevant chromophores these transitions are in the UV. Resonance enhancements are in the order of 10^4 – 10^5 for UV absorption bands. In order to measure these phenomena with fibre optic probes the problems posed by inherent signals produced in the delivery and collection system had to be overcome. Turner and co-workers have successfully built a fibre optic probe for UV resonance Raman spectroscopy (**Figure 14e**). UV-grade and solarization-resistant-UV-grade optical fibres (Poly-micro) are used for the collection and excitation path respectively. Their design incorporates an excitation fibre and an oblique polished fibre with a larger diameter to collect the scattered light (600 μm). This configuration minimizes inner filtering (sample self-absorbance). Because solutions are investigated a reflective surface based on a metallic coating is needed on the collection fibre. Aluminium reflects more than 90% at 250 nm.

Summary

A large variety of optical designs allow optimal illumination and light collection for spectroscopic applications. Specific solutions for fluorescence, reflectance and Raman spectroscopy are available and the possibility to combine them in a single probe is feasible. Future research will lead towards integrated, multifunctional and highly optimized fibre optic probes.

Fibres and Films Studied Using X-Ray Diffraction

Watson Fuller and Arumugam Mahendrasingam, Keele University, Stoke-on-Trent, UK

This article is reproduced from the previous edition, volume 1, pp 529–539, © 1999, Elsevier Ltd.

The fibrous state is a natural habit for those polymer molecules which, because of a high degree of regularity in their monomer sequence, tend to assume helical conformations rather than, for example, the less regular, although nevertheless highly organized, globular structures characteristic of many proteins. Such fibres typically contain regions in which the polymer molecules are arranged with their chain axes parallel to the fibre axis. This orientation is often associated with order in the side-by-side packing of the polymer chains so that the fibre can be regarded as consisting of an array of microcrystallites separated by less ordered regions. Generally there is no preferred orientation of these microcrystallites about the crystal axis parallel to the fibre axis. Consequently an X-ray diffraction pattern from such a crystalline fibre is similar to that which would be obtained from a single crystal if it were rotated through 360° about one of its principal axes during data collection. Although such rotation inevitably results in some loss of 3D information on the crystal structure, this loss is frequently much less significant than might be expected. Indeed the major expansion over the past few years in the use of powder diffraction, where the loss of information because of the complete absence of a preferred crystallite orientation is very much more extensive than that in oriented fibres, provides abundant evidence of the value of the information which can be obtained from studying specimens with a lower degree of order than that of single crystals. In this context it is important to emphasize that the degree of crystallinity in oriented fibres, as indicated by the upper limit in the angle of diffraction for which sharp Bragg diffraction peaks are observed, is often comparable with that observed for single crystals of proteins and other macromolecules. Many polymer materials are manufactured as films with a thickness of a few hundred micrometres. Since crystallite sizes in polymer films are typically a few tens of nanometres or less in lateral dimensions (i.e. approximately ten thousand times less than the film thickness) they can be analysed using similar methods to those used to study fibres.

The Relevance of X-Ray Diffraction Studies of Fibres and Films

Fibre diffraction is one of the most powerful and generally applicable techniques available for the study of

macromolecular structure. The validity of this claim may be demonstrated by the following points:

1. For many biological structures such as muscle and connective tissue, the fibrous state is functionally important and fibre diffraction techniques therefore allow both the structure of the macromolecules themselves and their organization in higher order structures to be investigated with the minimum of disturbance to the *in vivo* structure.
2. The technological value of many synthetic polymer materials can be related to their molecular conformation and arrangement, typically expressed in terms of the degree of polymer orientation and crystallinity. Fibre diffraction provides the opportunity to investigate these structures in functionally important situations, e.g. in commercially available sheets and fibres.
3. Because of the high degree of regularity in helical structures and the availability of information on covalent bond geometry from X-ray single crystal studies of model compounds, it is possible to describe the conformation of many fibrous polymers in terms of a relatively small number of parameters, i.e. the torsional angles about the various covalent single bonds. The use of such descriptions can have a dramatic effect on the ratio of observed data to parameters to be determined and hence on the accuracy with which fibrous structures can be determined.
4. The fibrous state is particularly well suited to the investigation of structural transitions in the conformation of polymer molecules and in their arrangement. Such investigations are of increasing importance in the study of both naturally occurring and synthetic polymers.
5. While many biological macromolecules can undergo conformational transitions, these are typically between well defined structures. In many cases these structures persist in a wide variety of molecular environments, e.g. the B form of the deoxyribonucleic acid (DNA) double-helix determined from X-ray fibre diffraction is observed with relatively little conformational variation in solution, in association with a number of different proteins and in fibres in a range of crystalline and semicrystalline arrays. Such observations comprise just one aspect of the large body of data which bears testimony to the biological relevance of structural information obtained from diffraction studies of macromolecules in fibres, films and single crystals.

Biological evolution exhibits a wealth of examples of the exploitation of polymer structure, with muscle a particularly impressive and intriguing example. The recognition that these biological structures have been refined over hundreds of millions of years in response to competitive pressures has prompted an increasing interest in using them as a source of ideas for the rational design of man-made materials and with it increasing emphasis on efforts to relate the structure of polymer materials to their physical properties.

The Impact of X-Ray Synchrotron Radiation Sources

The advent of dedicated X-ray synchrotron radiation sources, beginning with the Daresbury Laboratory Synchrotron Source (SRS) in 1981, dramatically extended the power and scope of X-ray diffraction studies of fibres and films. The high flux per unit area of the beam at the specimen position produced by such sources allowed diffraction patterns to be recorded with exposure times two or three orders of magnitude shorter than those required for a conventional rotating anode X-ray source. As a consequence it became possible to record within minutes complete 2D high angle X-ray fibre diffraction patterns which had previously required exposure times of hours. As third generation sources such as the European Synchrotron Radiation Facility (ESRF), Grenoble, together with corresponding improvements in beam line instrumentation, became available during the 1990s exposure times in the millisecond range became possible with the prospect of recording in real time changes in the X-ray diffraction pattern corresponding to changes in polymer conformation and organization. Such data is of central importance in investigating the relationship between structure and function in biological macromolecules and in relating the structure of industrial polymers to their bulk physical properties. The very high degree of collimation in radiation from sources such as the ESRF together with innovations in beam line optics has made it possible to reduce the diameter of the incident X-ray beam by two orders of magnitude from that typical of rotating anode sources and hence to allow structural variation in polymer materials to be recorded with a spatial resolution of ~ 1 micrometre. Since the radiation emitted from synchrotron sources comprises a continuous spectrum from X-rays to the far infrared it is possible to select the wavelength used in any particular experiment to match specific features in the absorption spectrum of the material being studied. In particular this 'wavelength tunability' offers the possibility of undertaking anomalous scattering experiments in which the wavelength of the incident X-rays is varied in the region of an atomic absorption edge. This approach has

considerable potential but, to date, its application in the study of polymer materials has been limited because of technical difficulties.

Two regimes are distinguished in X-ray diffraction studies of fibres and films according to whether they are in the domain of wide angle X-ray scattering (WAXS) or small angle X-ray scattering (SAXS). In WAXS, X-rays scattered through angles greater than $\sim 1^\circ$ to the incident X-ray beam are recorded. This typically provides information on structural features with dimensions in the range 5 nm to 0.1 nm, e.g. the detailed conformation and packing of polymer chains. In SAXS, X-rays scattered through angles less than $\sim 1^\circ$ to the incident X-ray beam are recorded. This typically provides information on structural features with dimensions in the range 100 nm to 5 nm, e.g. the overall folding and organization of polymer chains and the shape, size and distribution of crystallites. This distinction between the information which can be obtained from WAXS and that which can be obtained from SAXS illustrates the general principle in scattering theory that spacings in a diffraction pattern (i.e. the angle of scatter) are reciprocally related to the dimensions of features in the scattering object to which they relate.

The information which can be obtained in X-ray diffraction studies on fibres and films by the exploitation of synchrotron radiation sources is illustrated in this article by studies of both biological and man-made materials. All the studies were made at either the SRS or the ESRF but the techniques described are typical of those used at the rapidly increasing number of synchrotron sources available throughout the world. Examples of the data which can be obtained from highly ordered fibrous structures are illustrated for a WAXS pattern from DNA in **Figure 1** and a SAXS pattern from muscle in **Figure 2**. The possibility of recording real-time from the same specimen offers the possibility of relating changes in local polymer structure as revealed by WAXS to larger scale changes in polymer organization as revealed by SAXS. Increasingly, the information obtained from SAXS and WAXS on molecular structure and organization is complemented by the use of other techniques in which the recording of observations is synchronized to SAXS and WAXS measurements, e.g. stress/strain and calorimetric measurements in studies of the response of polymer materials to mechanical and thermal stress.

Experimental Facilities and Techniques

The radiation emitted from the electron storage rings at synchrotron radiation sources is typically channelled through a number of beam lines into some 30 or so work stations (**Figure 3**). The work stations vary in having their beam line optics designed to produce a beam

Figure 1 Wide angle X-ray fibre diffraction pattern recorded from the D form of the DNA double-helix.

Figure 2 Small angle X-ray fibre diffraction pattern recorded from plaice fish muscle.

with the cross-sectional area and degree of parallelism at the specimen which best matches the demands of the type of experiments to which they are dedicated. For X-ray diffraction studies of fibres and films the most common requirements are a highly monochromatic beam with a wavelength of ~ 0.1 nm and the highest possible X-ray intensity within a beam diameter ~ 100 μ m. On third generation sources such as the ESRF, microbeams with diameters of ~ 10 μ m or less are produced without unacceptable loss of intensity through collimation or a

loss of parallelism because of focusing elements. Loss of parallelism is of particular concern for SAXS studies because the more the incident X-ray beam is focused on the specimen, the more divergent will be the unscattered X-rays passing through the specimen and hence the larger the minimum angle at which scattered X-rays can be recorded and the lower the upper limit in the dimensions of structural features in the specimen on which information can be obtained. Monochromatization and focusing of the main beam are typically achieved using a variety of crystal monochromators and curved mirrors which reflect X-rays at glancing incidence often from surfaces coated with thin metal layers. The increased use of insertion devices such as undulators in straight sections of the electron storage ring in more recent synchrotron sources allows the radiation fed to particular work stations to be matched more closely to specific applications in terms of intensity as a function of wavelength. Such developments are of particular importance for diffraction studies where there is often a need to maximize the intensity in a very narrow wavelength range.

A variety of X-ray cameras have been developed for use on synchrotron radiation beam lines to provide a controlled environment in which the material to be studied can, for example, be subjected to particular conditions of relative humidity, thermal and mechanical stress. The capacity to control relative humidity is of particular importance for biological materials since *in vivo* they are commonly extensively hydrated. The processing of polymer materials typically involves exposing them to thermal and mechanical stress and cameras for studying them under industrial processing conditions typically incorporate drawing rigs able to apply various patterns of mechanical stress at well-defined temperatures. The front face of an X-ray camera normally accommodates a final collimating system defining the size of the X-ray beam falling on the specimen mounted close to the final aperture of the collimator. In some cameras the specimen mount incorporates a goniometer driven remotely which allows data to be collected as a function of the tilt of the fibre with respect to the incident X-ray beam. For the collection of WAXS data the distance between the front and rear faces of the camera is ~ 10 cm. For the collection of SAXS data this distance may be 1 m or even more if data corresponding to periodicities in the specimen of greater than 50 nm are to be collected. The detector on which the diffraction pattern is recorded is placed close to the rear face of the camera which is made from a material with low X-ray absorption such as a 10 μ m thick sheet of the plastic Melinex on which a lead backstop is mounted to absorb the component of the incident beam not scattered by the specimen. To reduce degradation of the data due to scattering by air of the X-ray beam not scattered or

Figure 3 Schematic representation of beam lines and work station at the ESRF.

absorbed by the specimen, the camera is evacuated or the air replaced by helium gas which is a much weaker scatterer of X-rays. Until relatively recently X-ray diffraction data from fibres was commonly recorded on photographic film. However, during the 1990s a variety of electronic area detectors have largely replaced film at synchrotron sources. One of the most important advantages of electronic area detectors of the gas filled multiwire and CCD types is that they allow the diffraction pattern to be displayed in real time so that experiments can be genuinely interactive. In contrast, it may take 10 or 15 min to process film. This time does not of course include scanning of the processed film as a necessary preliminary to accurate determination of the position and intensity of diffraction spots. In contrast, data recorded

electronically can be immediately downloaded to an online computer for data reduction and analysis. In deciding between different types of detector it is important to compare parameters such as:

1. *spatial resolution* – the grain size on X-ray film is typically less than $10\ \mu\text{m}$ and although electronic area detectors generally available have significantly worse resolution than this, they are adequate for recording fibre diffraction data;
2. *quantum efficiency* – depends critically on the wavelength of the X-rays; therefore while comparisons with film are complex it is fair to say that state-of-the-art electronic area detectors can show efficiency comparable to film;

3. *dynamic range* – the limited dynamic range of film is one of its major limitations and an area where its performance is generally inferior to electronic area detectors.

Image plates have a spatial resolution comparable to film with a much larger dynamic range. However, they still suffer from the need for scanning which, even with ingenious online carousels and dedicated scanners, still makes it impossible to conduct genuinely real-time interactive experiments. The examples of diffraction data included in this review illustrate the use of the various types of detector.

Examples of the Exploitation of X-Ray Diffraction Using Synchrotron Radiation in the Study of Fibres and Films at High Temporal and Spatial Resolution

These examples are chosen to illustrate the impact of both WAXS and SAXS studies on the characterization of naturally occurring and man-made materials. These studies exploit both the greatly increased intensity and

much reduced divergence in the X-ray beam available from synchrotron sources as compared with that from laboratory rotating anode X-ray sources.

Conformational Transitions in the DNA Double-Helix

The original proposal of a double helical structure for DNA was based on wide angle X-ray fibre diffraction data. Subsequently, a number of distinct conformations of the double-helix have been observed and designated A, B, C, D and Z. The sensitivity of the conformation of the DNA double-helix to its degree of hydration allows conformational transitions to be induced by changing the relative humidity of the fibre environment. The availability of X-ray synchrotron radiation sources offers the possibility of observing the variation in diffraction data during such transitions with the possibility of describing the stereochemical pathway followed during the transition. In an early application of the Daresbury SRS the reversible transition between the B and D conformations was followed through a number of cycles. Selected fibre diffraction patterns from this transition are in **Figure 4**. The transition between the D and B conformations can

Figure 4 Diffraction patterns illustrating typical stages in the D to B transition in the DNA double-helix. In (a) the reflection marked I is related to the lateral intermolecular separation and that marked II to the helical pitch of molecules in the D form. In (c) the reflection marked III is related to the lateral intermolecular separation and that marked IV to the helical pitch of molecules in the semicrystalline intermediate form.

be followed through the appearance in the original highly crystalline D pattern of reflections corresponding to a semicrystalline intermediate between the D and B forms. As the transition proceeds, these reflections become more intense, corresponding to an increasing fraction of the DNA assuming the semicrystalline phase, and gradually change in position corresponding to a continuous change in helix pitch from the 2.4 nm characteristic of the crystalline D form to the 3.4 nm characteristic of the semicrystalline B form. The diffraction data on which this analysis was based were recorded on photographic film with exposure times of a few minutes. In the next 10 years after these studies were made major advances in both synchrotron performance and detectors have dramatically decreased the exposure times required for such time-resolved studies.

Changes in Molecular Organization and Interactions during Muscle Contraction

Muscle is a complex assembly of proteins embracing the metabolic capabilities characteristic of globular proteins and the structural capabilities of fibrous proteins and is thus well suited to perform the dual roles of converting chemical energy into mechanical energy and sustaining tension. Over 40 years ago a combination of electron microscopy and X-ray fibre diffraction showed that muscle consisted of a regular array of actin filaments interpenetrating a regular array of myosin filaments and that during muscular contraction one family of filaments slid over the other. The dimensions of these arrays and the periodicities along the length of the actin and myosin filaments are within the 10 to 100 nm range and X-ray fibre diffraction information on these structures has largely come from the small angle regime. A particularly well-defined example of such SAXS data is in **Figure 2**. The high brilliance of synchrotron sources together with recent advances in the efficiency of multiwire area detectors have allowed the variation in diffraction during the contraction cycle, in which a dissected muscle is repeatedly stimulated by an electrical voltage, to be recorded with a time resolution of a few milliseconds. This data is being used to model changes in the interaction between the actin filaments and the heads of the myosin molecules making up the myosin filaments since it is believed that changes in the stereochemistry of these interactions is the origin of the mechanical stress which results in shortening in the length of the muscle against a load. This modelling is an excellent example of complementarity between an X-ray structure determination of a protein single crystal (in this case the structure of isolated myosin heads) and a small angle X-ray fibre diffraction study of the whole muscle assembly.

Strain-Induced Crystallization in Poly(Ethylene Terephthalate) (PET)

One of the most challenging issues in the crystallization of polymers is the nature and kinetics of the strain-induced crystallization that takes place when polymers such as PET are mechanically drawn close to the glass transition temperature. From experiments at the ESRF and SRS, it has been possible to monitor crystallization in real-time when amorphous PET was drawn at rates comparable to those used in industrial processing. The X-ray camera used in these studies consisted of a 150 mm $\times$ 150 mm $\times$ 150 mm oven of which three sides were inter-changeable so that it was possible to exchange sides depending on the particular application. This, for example, allowed the viewing port in which a video camera was mounted to be varied. The temperature could be controlled to within 1 °C and the maximum temperature attainable was 350 °C. A strip of polymer material could be clamped between two jaws attached to stepper motors which allowed uniaxial bidirectional drawing at rates up to 72 000% per minute. Diffraction patterns were recorded with exposure times of 40 ms. The variation in WAXS in a typical experiment is shown in **Figure 5**. In this sequence of patterns the sharp crystalline peaks can be seen to progressively emerge above a diffuse background scatter. Simultaneously recorded video camera observations on changes in the position of reference marks on the specimen are also shown in **Figure 5** and allow the precise draw ratio and draw rate to be calculated at the point in the specimen from which X-ray diffraction data was recorded. Measurements on these patterns allowed the development of polymer orientation and crystallinity to be quantified and hence the kinetics of crystallization to be determined for a number of temperatures and for a variety of draw rates and draw ratios. An important conclusion from these studies, which is at variance with earlier conclusions drawn from studies on samples quenched at various stages during drawing and annealing, is that, at the fast draw rates typical of industrial processing, significant crystallization does not begin until the conclusion of drawing. When the rate constants determined from these experiments were related to theoretical models for the relaxation of deformed chains within entangled networks it became clear that at fast draw rates the onset of crystallization does not occur until the end of draw because the draw rate exceeds the rate of chain relaxation.

Relation between Long- and Short- Range Order during Deformation of Polyethylene

Instrumentation for simultaneous recording of SAXS and WAXS data is illustrated schematically in **Figure 6**. A hole, $\sim$ 10 mm diameter, in the centre of the 15 μ m

Figure 5 WAXS patterns with corresponding video image of a sample of PET recorded during drawing at 90 °C at an overall draw rate of 72 000% / min. Each of the 31 frames was recorded with an exposure time of 40 ms. There was essentially no dead time between frames so that the drawing experiment was completed in ~ 1.2 s.

thick aluminium foil through which diffraction beams exit the camera is covered with a circular glass cover slip (13 mm in diameter; and 15 μm thick) so that the SAXS and the main beam not scattered by the specimen pass wholly through the glass cover slip. This avoids diffraction of the main beam by the aluminium resulting in spurious sharp diffraction peaks in the WAXS pattern. Both SAXS and WAXS data were recorded using Photonic Science CCD detectors. An evacuated beam pipe was positioned between the SAXS detector and the glass

cover slip mounted on the aluminium foil to minimize scattering by air along the long path length. The WAXS detector was positioned close to the aluminium foil window at the rear of the camera so that SAXS data could still pass unobstructed for collection at the second CCD detector.

A specimen, 10 mm wide and 20 mm long, was cut from a 1 mm thick sample of high density polyethylene and mounted within the camera in jaws attached to stepper motors. The specimen was drawn at a rate of

Figure 6 Schematic representation of the experimental arrangement for simultaneous recording of SAXS/WAXS and strain data during mechanical deformation of a sheet of polymer material.

Figure 7 Selected pairs of simultaneous WAXS (left) and SAXS (right) frames with inserts of correspondingly synchronously recorded video images which allow strain data to be related to changes in polymer structure and organization of high density polyethylene. Each frame was recorded in 40 ms.

18 000%/minute at a temperature of 35 °C. Strain data, for the region of the specimens from which the SAXS/WAXS data was collected, was calculated from an accurately synchronized continuously recorded video image of the specimen. **Figure 7** shows selected SAXS and WAXS frames recorded from the specimen. In the initial WAXS frame two rings of intensity are clearly visible. These may be indexed as reflections from the orthorhombic form of polyethylene. The initial SAXS

frame consists of a largely isotropic ring indicating that the undeformed sample is spherulitic with a lamellar spacing of ~ 35.0 nm. From the sequence of WAXS patterns it is apparent that increasing strain results in increasing orientation in both of the prominent orthorhombic reflections together with the transient appearance of a monoclinic phase. The SAXS patterns show striking variation in intensity which can be attributed to the formation of microvoids.

Variation in Crystallite Order and Orientation in Spherulites of Biopol

X-ray diffraction provides one of the most powerful techniques for the investigation of the spatial variation of polymer conformation and organization within partially ordered materials. From optical microscopy it is clear that molecular orientation within many polymer materials varies over dimensions of less than $100\text{ }\mu\text{m}$. Characterization of this variation by X-ray diffraction has been achieved using the microfocus capability of the ESRF which can provide an intense highly monochromatic X-ray beam with a wavelength of 0.092 nm in a beam diameter at the specimen of $\sim 10\text{ }\mu\text{m}$. Crucial to these experiments was the availability of a computer-controlled X/Y stage which allowed the specimen to be tracked in two dimensions perpendicular to the X-ray beam in steps as small as $1\text{ }\mu\text{m}$ (Figure 8). WAXS data were recorded using a Photonics Science CCD detector from spherulites of the optically active thermoplastic polymer Biopol. This material is produced by a variety of microorganisms, which use it for energy and carbon storage. The biological rather than petroleum origins of Biopol, its biodegradability, and its ability to form films

Figure 8 Experimental arrangement for recording WAXS data with high spatial resolution. A backstop to absorb unscattered X-rays is suspended immediately before the detector.

with the properties of conventional thermoplastics give it technological importance as well as fundamental interest. The purity of the polymer leads to an absence of heterogeneous nuclei and gives it the capacity to form large spherulites of high crystallinity. X-ray diffraction patterns with exposure times of 1 s were recorded as a spherulite of Biopol was stepped across a square net of area $150\text{ }\mu\text{m} \times 150\text{ }\mu\text{m}$ centred on the centre of the spherulite, in horizontal and vertical steps of $10\text{ }\mu\text{m}$. The 15×15 diffraction patterns recorded in this way are assembled as a 2D array in Figure 9. This array of patterns vividly demonstrates that all the crystallites have their *a*-axes oriented along a radius of the spherulite.

Variation in Polymer Orientation and Crystallinity across a Plastic Bottle Wall

PET is used extensively in the manufacture of fibres, bottles and films. Physical properties, such as strength, transparency and gas-transport properties, depend on the degree of polymer orientation and crystallinity and their variation in the artefact.

During blowing of a bottle, the inner surface of a preform is cooled by the expansion of the compressed air used for inflation, the outer surface is cooled by contact with the cold mould whilst the internal thermal energy is raised by strain heating. In addition, the contour shape of

Figure 9 X-ray fibre diffraction patterns from the region of the spherulite of Biopol illustrated in the inserted polarizing microscope image. Each pattern was recorded from an area $10\text{ }\mu\text{m}$ in diameter with its position in this figure corresponding to the position in the specimen from which it was recorded. Each crystallite is oriented with its *a*-axis radial; the degree of orientation decreases towards the centre of the spherulite.

Figure 10 Variation of crystallite size, crystallinity and polymer orientation as a function of position in the wall of a PET bottle. The X-ray diffraction patterns were selected from the 32 frames recorded during the experiment. Frame 1 was collected at the inside face of the bottle wall, whilst frame 32 was collected at the outside face.

the container and the complex blowing process itself produces considerable variation in wall thickness and direction of stretching at different positions in the container. The polymer therefore experiences a wide variation in draw temperature, draw ratio and draw direction at different positions of the container and at different depths in the wall, resulting in a wide variation of polymer orientation and crystallinity.

The sample for X-ray microbeam examination was prepared by cutting a 1 mm square piece from the container and mounting it on an X/Y stage so that it could be tracked across the X-ray beam. **Figure 10** shows selected frames from a dataset comprising 32 frames. The patterns show a marked variation in crystallinity through the thickness of the wall. At the inside edge there are strong oriented crystalline reflections superimposed on a fairly isotropic amorphous halo. The intensification of the crystal reflections around the equator is consistent with preferential chain alignment along the longitudinal axis of the bottle. The intensity of the crystal reflections diminishes towards the centre of the wall thickness, leaving an almost isotropic amorphous diffraction halo.

Nearer the outer edge of the wall there is an intensification of the halo on the equator indicating an increasing degree of orientation in the disordered chains. These observations can be related to variation in the local draw rate, draw ratio and temperature across the wall during fabrication and provide a basis for refining the manufacturing process to produce bottles of improved performance.

Introduction

The mass spectra of molecules, ionized by electron ionization (EI), field ionization (FI) or photoionization (PI) in the gas phase, usually show many peaks with varying intensities. These peaks result from fragment ions generated by a series of competing and consecutive unimolecular dissociation reactions of the molecular ions provided that the latter have obtained during their formation an amount of energy in excess of the ionization energy of the corresponding molecules. The resulting mass spectrum therefore is determined by the relative rates of these unimolecular dissociation reactions, which in their turn are related to the relative abundances of the fragment ions observed. It will be clear that studying the kinetics of ion dissociation can provide an invaluable insight into the foundation of a mass spectrum.

Although trapped-ion mass spectrometry has been used to investigate the extent of fragmentation of ions as a function of time in the time range of μs to ms , another and unique method is that of field ionization kinetics (FIK). The roots of this method date from the work of Beckey at the University of Bonn, Germany, who interpreted (as early as 1961) the broadening of peaks in field ionization (FI) mass spectra, obtained with a single-focusing mass spectrometer, as a consequence of ion lifetimes. Picosecond resolution of these ion lifetimes was achieved in 1971 by Derrick and Robertson at King's College in London, United Kingdom on the basis of a thorough calibration of the time-scale following FI. Since then the development of the experimental techniques to measure such ion lifetimes and of the necessary theory of the corresponding ion decomposition rates have led to the use of the name FIK. With this method the rates of gas phase unimolecular decompositions of ions, occurring

at times as short as picoseconds and over a time range of seven orders of magnitude (10^{-12} – 10^{-5} s), and corresponding ion lifetimes can be measured.

Following a description of the principle of the FIK method, some illustrative examples of its application in gas-phase ion chemistry studies will be presented.

Principle of the FIK Method

FIK experiments are performed on double-focusing mass spectrometers having either the conventional (the electric sector precedes the magnetic sector) or the reversed (the magnetic sector precedes the electric sector) geometry. A schematic diagram of a field ionization double-focusing mass spectrometer with the conventional geometry is given in **Figure 1**.

Ions are generated in a very narrow region close to an anode (in the case of positive ions). This region becomes less narrow as the anode is changed from a tip, to a blade to a $1\text{ }\mu\text{m}$ bare tungsten wire or to a $10\text{ }\mu\text{m}$ activated tungsten wire (**Figure 2**) at a potential V_0 (~ 8 – 10 kV) with respect to a slotted cathode at ground potential and at a distance that is increased from 0.25 to 1.5 mm.

If these ions are stable for $\geq 10^{-5}$ s, they will acquire a kinetic energy qV_0 during acceleration from the ionization region (where to a good approximation the potential is equal to the anode potential V_0) to the slotted cathode and will pass the electric sector set to transmit ions with a kinetic energy qV_0 . Consequently, they will be mass analysed at their correct m/z values if the magnetic field is scanned. In this way, an FI spectrum is obtained which contains peaks that correspond to the ions generated very near the anode, i.e. within approximately 10^{-11} s. Fragment ions m^+ (see eqn [1]), generated in unimolecular dissociation reactions that occur between the anode and cathode (region I in **Figure 1**) at a potential V_x , will not be transmitted through the electric sector because they have insufficient kinetic energy $[q(m/M)(V_0 - V_x) + qV_x]$ to be focused by this sector.

However, these ions can be transmitted through the electric sector by either decreasing its potential at a constant anode potential V_0 or by increasing the anode potential at a constant electric sector potential set to

Figure 1 Schematic diagram of a double-focusing field ionization mass spectrometer of conventional geometry (not drawn to scale), showing the four regions in which field ionization kinetic measurements can be made. Figure 2 Scanning electron micrograph of a 10 μm tungsten wire covered with carbon microneedles grown by activation.

transmit ions with a kinetic energy qV_0 . The most widely used method involves increasing the anode potential.

The determination of the amount, ΔV , with which the anode potential V_0 has to be increased to satisfy eqn [2] permits a calculation of the potential V_x at which reaction [1] has occurred.

$$qV_0 = q(m/M)(V_0 + \Delta V - V_x) + qV_x \quad [2]$$

It is then possible to calculate the ion lifetime, i.e. the time elapsed between formation of the molecular ion M^{*+} and its subsequent fragmentation at potential V_x , if the potential distribution between the anode and cathode is known. Thus, a scan of the anode potential achieved by increasing ΔV allows one to monitor reaction [1], following FI of M over a continuous time range of $\sim 10^{-11}$ – 10^{-9} s (region I in **Figure 1**). The required, time-consuming data processing can be speeded up by use of an online computer,

which also enables computer-controlled data acquisition and multiscan averaging to enhance the signal-to-noise ratio of the usually weak FIK signals.

Decompositions of M^{*+} ions at times longer than 10^{-9} s can be investigated in the focusing region II and in the first and second field-free regions III and IV (**Figure 1**) by using metastable ion methods.

The experimental results take the form of curves of product ion current $I_m(t)$ versus kinetic energy, which are transformed according to the principles outlined above into curves of product ion current $I_m(t)$ versus reaction time t . The product ion current $I_m(t)$ is related to the rate of reaction, $dI_m(t)/dt$, by eqn [3], where Δt is a small interval within which decomposing M^{*+} ions contribute to the product ion current $I_m(t)$ at time t :

$$\frac{dI_m(t)}{dt} = \frac{I_m(t)}{\Delta t} \quad [3]$$

This interval is determined by the energy resolution of the electric sector and depends on the molecular and product ion masses and on the reaction time t , i.e. this time window interval will decrease with increasing mass difference between the molecular and product ions (not unlimited because of the difficulties in increasing the anode potential due to arcing problems) and at shorter decomposition times of the molecular ions because of the increase of the electric field gradient with decreasing distance from the anode.

Division of eqn [3] by the measured mass-resolved molecular ion current I_M at an anode potential V_0 , i.e. in the normal FI spectrum, yields the so-called normalized rate $k(t)$:

$$k(t) = I_m(t)/I_M \Delta t \quad [4]$$

Plots of $k(t)$ versus t obtained with different mass spectrometers, different anodes and different ion lifetime

calculations have been shown to be reproducible to within 25%.

The normalized rate $k(t)$ is related to the time-independent rate constant $k(E)$ as defined by the quasi-equilibrium theory (QET) in the following way. Suppose that the molecular ions $M^{\bullet+}$ decompose via a single channel to fragment ions m^+ . If the $M^{\bullet+}$ ions have acquired an internal energy E upon FI, their abundance $M(t)$ at time t will be given by

$$M(t) = M_0 e^{-k(E)t} \quad [5]$$

where M_0 is the abundance of the molecular ions at the time of their formation. The rate of formation of the fragment ions m^+ is then given by

$$dm^+/dt = k(E) M(t) = k(E) M_0 e^{-k(E)t} \quad [6]$$

The molecular ions $M^{\bullet+}$, however, will have acquired a distribution of internal energies, $P(E)$, upon FI. In this case all individual rates of formation of m^+ given by eqn [6] have to be summed with respect to the internal energy E . This leads to eqn [7] with $P(E)$ as the weighting function and $I_m(t)$ as the product ion current at time t (see above):

$$\frac{dI_m(t)}{dt} = \int_0^\infty P(E) k(E) M_0 e^{-k(E)t} dE \quad [7]$$

Similarly, the molecular ion current I_M is obtained by integration of eqn [5] with respect to the internal energy E , taking $P(E)$ as the weighting function:

$$I_M = \int_0^\infty P(E) M_0 e^{-k(E)t} dE \quad [8]$$

Division of eqn [7] by eqn [8] then gives the relation between the normalized rate $k(t)$ and the time-independent rate constant $k(E)$:

$$k(t) = \frac{\int_0^\infty P(E) k(E) e^{-k(E)t} dE}{\int_0^\infty P(E) e^{-k(E)t} dE} \quad [9]$$

Usually a maximum is observed in the $k(t)$ versus t plots. The maximum has been suggested to represent $k_{\max}(E)$ in the distribution of $k(E)$ s and generally occurs at longer times for rearrangement reactions than for simple cleavage reactions. These reactions usually compete with each other continuously over the time range of 10^{-11} – 10^{-5} s.

The vertical axis covers $\log k(t)$ values in the range of 8–12. Reproduced with permission from Zappey HW, Ingemann S, and Nibbering NMM (1991) Study of the rate of methyl loss and the structure of the product ion as a function of the lifetime of the molecular ion of penten-3-en-2-ol. *Organic Mass Spectrometry* 26: 241–246.

An example of a logarithmic plot of $k(t)$ versus t for the loss of a methyl radical from the molecular ion of pent-3-en-2-ol, $\text{CH}_3\text{CH}=\text{CHCH}(\text{OH})\text{CH}_3$, is given in **Figure 3**.

The figure shows two maxima. The first maximum at a molecular ion lifetime of $10^{-10.5}$ s corresponds to the loss of a methyl radical from the unrearranged molecular ion via a direct cleavage reaction, whereas the second maximum at a molecular ion lifetime of $10^{-10.1}$ s is due to the loss of a methyl radical following a rearrangement reaction of the molecular ion.

The strength of FIK in mechanistic gas-phase ion dissociation studies compared with the conventional EI method is that it gives a time-resolved view of the chemistry and isomerization reactions of ions over a time range of 10^{-12} – 10^{-5} s. The details of these processes are largely lost in the EI method which integrates all the events up to 10^{-6} s following ionization, a very broad time range compared with the vibrational periods of chemical bonds (10^{-14} – 10^{-13} s).

The strength of the FIK method in mechanistic ion dissociation studies is shown to full advantage when it is used in combination with stable isotopic labelling. In that case, the fragment ions from competing reactions are nearly equal in mass so that the ratios of their ion currents measured at any time t are practically equal to the ratios of the normalized rates $k(t)$ (see above and eqn [4]). Most of the mechanistic ion dissociation studies discussed below are therefore based upon changes in relative rates as a function of the ion lifetimes.

Scheme 1

Mechanistic Ion Dissociation Studies

Four examples of the application of FIK to mechanistic ion dissociation studies will be presented.

The first deals with the elimination of ethylene from the molecular ion of cyclohexene, the second and third with the dynamics of stereochemically controlled dissociation reactions and the fourth with time-resolved MS-MS to identify the structures of product ions generated at different molecular ion lifetimes.

Elimination of Ethylene from the Molecular Ion of Cyclohexene

In both linear and cyclic alkene EI-generated molecular ions, the double bond shifts before or during fragmentation,

Scheme 2

Scheme 3

and this causes the mass spectra of isomers to be very similar, if not indistinguishable. The same is true for the EI-generated molecular ion of cyclohexene, in which specific D-labelling has shown a practically statistical distribution of H and D atoms over the carbon skeleton before or during fragmentation.

Upon FI, four variously deuterated ethylene molecules, C_2H_4 , $\text{C}_2\text{H}_3\text{D}$, $\text{C}_2\text{H}_2\text{D}_2$, and C_2HD_3 , are eliminated from cyclohexene-3,3,6,6- d_4 .

At 10^{-11} s, more than 50% is lost as C_2H_4 , but at longer times a rapid increase of the loss of the deuterated ethylene molecules is observed until at 10^{-9} s a statistical distribution of the H and D atoms has occurred before decomposition. The specific loss of C_2H_4 at 10^{-11} s can readily be explained by a retro-Diels–Alder reaction of the molecular ion to give the ion m/z 58 (Scheme 1). The interesting observation made, however, is that the maximum rates of the variously labelled ethylene eliminations occur at different times; the order with increasing time is $\text{C}_2\text{H}_4 < \text{C}_2\text{H}_2\text{D}_2 < \text{C}_2\text{HD}_3 < \text{C}_2\text{H}_3\text{D}$. This has been rationalized by invoking 1,3-allylic H/D shifts in the molecular ions before the retro-Diels–Alder reaction.

As can be seen from eqn [10], the formation of m/z 58, 56, 55 and 57 requires 0, 1, 2 and 3 allylic 1,3-H/D shifts, respectively, which coincides with the shift of the maximum rate of the corresponding ethylene eliminations to longer times.

Scheme 4 Double hydrogen transfer in the molecular ion of the *endo* isomer [2] of 8,9-disubstituted-tricyclo[5.2.1.0^{2,6}]decene not possible in the molecular ion of the *exo* isomer [1] followed by elimination of C₅H₈ via a retro-Diels-Alder reaction. Reproduced with permission of the American Chemical Society from Klufft E, Nibbering NMM, Kühn H, and Herzsuh R (1986) Dyotropic hydrogen rearrangement in the molecular ions of 8,9-disubstituted tricyclo [5.2.1.0^{2,6}] decenes as supported by field ionization kinetics. *Journal of the American Chemical Society* 108: 7201–7203.

Loss of a Molecule of Water from the Molecular Ions of Stereoisomeric Cyclohexane Diols

An FIK study of the water loss from stereoisomeric cyclohexane diols has shown how elegantly this method can give an insight into the dynamics of unimolecular decompositions of organic ions. This is especially true for the *trans*- and *cis*-1,3- and 1,4-diols, which generate relatively abundant (M–H₂O)^{•+} ions upon FI, in contrast with the *trans*- and *cis*-1,2-diols. The latter compounds yield low-abundant (M–H₂O)^{•+} ions, which is probably due to a fast cleavage of the C₁–C₂ bond of the molecular ions.

The 1,3-*d*₂ analogue of *trans*-cyclohexane-1,3-diol and the 1,4-*d*₂ analogue of the *trans*-1,4-diol molecular ions predominantly lose water by a transannular 1,3- and 1,4-elimination, respectively, as determined by using FIK. In both cases the normalized rate for this process reaches a maximum value at an ion lifetime of about 110 ps, but the rate is also significantly higher for the *trans*-1,3-diol than for the *trans*-1,4-diol at shorter ion lifetimes. The explanation for these observations is the following: both in the molecular ion of the *trans*-1,3-diol and in that of the *trans*-1,4-diol the hydroxyl group has to come in close proximity of the hydrogen atom to be transferred to effect the water elimination. This is the case for the two identical ground-state chair conformations of the *trans*-1,3-diol, which have a distance of 2.5 Å between the oxygen atom of the hydroxyl group and the hydrogen atom to be transferred, and for the corresponding boat conformation, as shown in (Scheme 2).

Scheme 5 Routes for methyl loss from ionized pent-3-en-2-ol. Figure 4 Losses of C_5H_6 , $C_5H_7^+$ and C_5H_8 , expressed in percentages of their sum, as a function of the lifetime of the molecular ions of (a) *exo*- and (b) *endo*-8,9-dimethoxytricyclo[5.2.1.0^{2,6}] decenes. Reproduced with permission of the American Chemical Society from Kluff E, Nibbering NMM, Kühn H, and Herzschuh R (1986) Dyotropic hydrogen rearrangement in the molecular ions of 8,9-disubstituted tricyclo [5.2.1.0^{2,6}] decenes as supported by field ionization kinetics. *Journal of the American Chemical Society* 108: 7201–7203.

However, for the *trans*-1,4-diol, only the boat conformations have the appropriate geometry for the transannular 1,4-elimination of water, as shown in (Scheme 2).

Similar arguments apply to the enhanced transannular loss of water from *cis*-cyclohexane-1,3-diol versus that

from the *cis*-1,4-diol. The departing water now contains both hydroxyl hydrogen atoms, as shown by D labelling. In both cases the normalized rate for this reaction again reaches a maximum value at ion lifetimes of about 110 ps.

Dyotropic Hydrogen Rearrangement in the Molecular Ions of 8,9-Disubstituted-Tricyclo[5.2.1.0^{2,6}] Decenes

Upon EI the *exo* and *endo* isomers of the 8,9-disubstituted-tricyclo[5.2.1.0^{2,6}] decenes [1] and [2], respectively, fragment essentially differently. The ionized *endo* isomers [2] eliminate C₅H₈ via a retro-Diels–Alder reaction after migration of the hydrogen atoms from positions 8 and 9 to the double bond. This reaction is not observed for the *exo* isomers [1] where the distance between the hydrogen atoms of positions 8 and 9 and the double bond is too large for the hydrogen migration required to effect the retro-Diels–Alder reaction (Scheme 4).

From these observations, however, it cannot be concluded whether the double hydrogen migration in ionized [2] occurs in a concerted or stepwise fashion. If the hydrogen atoms would migrate in a concerted fashion, then it is an example of a dyotropic reaction, being defined as an uncatalysed process in which two σ -bonds simultaneously, but not necessarily via a fully symmetrical mode, migrate intramolecularly. Such a

Figure 5 Losses of CH₃[•] and CD₃[•] expressed in percentages of their sum, as a function of the lifetime of the molecular ion of pent-3-en-2-ol-1,1,1-d₃, CH₃CH=CHCH(OH)CD₃. Reprinted from the *International Journal of Mass Spectrometry and Ion Physics* 38: Zwinselman JJ, Nibbering NMM, Middlemiss NE, Vajda JH, and Harrison AG, A field ionization kinetics and metastable ion study of the fragmentation of some pentenols, 163–179, Copyright 1981, with permission from Elsevier Science.

Figure 6 Collision-induced dissociation MS-MS spectra of (M-methyl)⁺ ions, generated upon FI from the molecular ion of pent-3-en-2-ol at molecular ion lifetimes of (a) $\leq 10^{-10.6}$ s and (b) $10^{-10.0}$ s. Reproduced with permission from Zappey HW, Ingemann S, and Nibbering NMM (1991) Study of the rate of methyl loss and the structure of the product ion as a function of the lifetime of the molecular ion of penten-3-en-2-ol. *Organic Mass Spectrometry* 26: 241–246.

Figure 7 Reference collision-induced dissociation MS-MS spectra of (a) protonated crotonaldehyde [4] and (b) protonated methyl vinyl ketone [7]. Reproduced with permission from Zappey HW, Ingemann S, and Nibbering NMM (1991) Study of the rate of methyl loss and the structure of the product ion as a function of the lifetime of the molecular ion of penten-3-en-2-ol. *Organic Mass Spectrometry* 26: 241–246.

suprafacial dyotropic transfer of hydrogen is a thermally 'allowed' [$\sigma 2_s + \sigma 2_s + \pi 2_s$] pericyclic reaction.

Experimental support for either a concerted or a stepwise double hydrogen migration in ionized [2] before elimination of C_5H_8 via a retro-Diels–Alder reaction (Scheme 4) is obtained from application of FIK to both *exo* and *endo* isomers [1] and [2] respectively.

For example, the *exo* isomer [1a] with $R^1 = R^2 = OCH_3$ appears to eliminate, exclusively, C_5H_6 over all molecular ion lifetimes studied, while the corresponding *endo* isomer [2a] eliminates both C_5H_6 and C_5H_8 , but not $C_5H_7^+$, see Figures 4a and 4b, respectively.

As expected, the C_5H_8 loss is a delayed process with respect to the C_5H_6 loss because of the required double hydrogen rearrangement, i.e. this channel starts to compete with the C_5H_6 loss at molecular ion lifetimes of $\sim 10^{-10}$ s and becomes dominant beyond molecular ion lifetimes of $\sim 10^{-9.25}$ s. Important, however, is the absence of $C_5H_7^+$ loss, which is expected to occur for a stepwise, but not for a concerted, double hydrogen rearrangement.

Methyl Loss from Ionized Pent-3-en-2-ol, $CH_3CH = CHCH(OH)CH_3$

A combined FIK and deuterium labelling study has revealed three pathways for the loss of methyl from the molecular ion of pent-3-en-2-ol, $CH_3CH = CHCH$

$(OH)CH_3$. This is shown by the relative rate curves for loss of CH_3^+ and CD_3^+ from the molecular ion of pent-3-en-2-ol-1,1,1- d_3 , $CH_3CH = CHCH(OH)CD_3$ in Figure 5.

At short ion lifetimes, CD_3^+ is the major loss, whereas at medium ion lifetimes CH_3^+ elimination is the major channel. At longer ion lifetimes the CD_3^+ loss again becomes increasingly important.

These observations have been rationalized mechanistically in Scheme 5.

Route [3] $\rightarrow$ [4] is operative at ion lifetimes $< 10^{-10.5}$ s and is suggested to lead to oxygen protonated crotonaldehyde, route [3] $\rightarrow$ [5] $\rightarrow$ [6] $\rightarrow$ [7] is dominant at ion lifetimes between $10^{-10.5}$ and 10^{-9} s and is suggested to lead to oxygen protonated methyl vinyl ketone, while route [3] $\rightarrow$ [5] $\rightarrow$ [8] $\rightarrow$ [9] increases at longer ion lifetimes and is suggested to produce the butyryl cation (Scheme 5).

The existence of different pathways is also indicated by the normalized rate curve for methyl loss from the molecular ion of unlabelled pent-3-en-2-ol, which contains two distinct maxima at ion lifetimes of $10^{-10.5}$ and $10^{-10.1}$ s after ionization (Figure 3).

In the normalized rate curve for CD_3 loss from the molecular ion of $CH_3CH = CHCH(OH)CD_3$ similar maxima are observed, but in that for CH_3 loss only the maximum at $10^{-10.1}$ s is present. This means that the maximum at $10^{-10.5}$ s corresponds to the route [3] $\rightarrow$ [4] of Scheme 5, as expected for such a direct cleavage

reaction, and that the maximum at $10^{-10.1}$ s is from the route $[3] \rightarrow [5] \rightarrow [6] \rightarrow [7]$ of **Scheme 5**. The ions [4 and 7] (and also [9]) formed by the different pathways are known to be non-interconverting species with distinct collision-induced dissociation mass spectra. Collision-induced dissociation experiments on the (M-methyl)⁺ ions, formed at different molecular ion lifetimes, i.e. at times $<10^{-10.6}$ and $10^{-10.0}$ s after ionization, have provided experimental support for their structures. The resulting time-resolved MS-MS spectra, in which the peaks are rather noisy owing to their low intensities, are presented in **Figure 6**.

The collision-induced dissociation MS-MS spectra of the independently made reference ions obtained by protonation of crotonaldehyde (ion [4] in **Scheme 5**) and methyl vinyl ketone (ion [7] in **Scheme 5**) are shown in **Figure 7**.

Figure 6a appears to match well **Figure 7a** which provides evidence that most of the (M-methyl)⁺ ions formed at about $10^{-10.6}$ s have the protonated crotonaldehyde structure, i.e. ion [4] in **Scheme 5**.

Figure 6b is nearly identical to **Figure 7b**, showing that the (M-methyl)⁺ ions at about $10^{-10.0}$ s have indeed, predominantly, the protonated methyl vinyl ketone structure, i.e. ion [7] in **Scheme 5**.

Introduction

The application of modern spectroscopic analysis to the study of flames began in the 1920s and 1930s with breakthroughs in the understanding of atomic and molecular spectroscopy. The earliest spectroscopic investigations focused on understanding the line and band structure observed in the visible and ultraviolet regions

of the spectrum when the light from the flame was dispersed by a grating or prism. One of the great breakthroughs of physics during this period was the understanding that the band structure observed in the emission spectra of flames originated from gas-phase molecular species.

For molecular species, understanding the appearance of flame spectra is simplified by assuming that the total internal energy, E_T , of a gas-phase molecule may be given to first order (Born Oppenheimer approximation) as:

$$E_T = E_{EL} + E_{VIB} + E_{ROT} \quad [1]$$

Here, E_{EL} , E_{VIB} , and E_{ROT} are respectively the quantized electronic, vibrational, and rotational energy of the molecular species. In the scientific literature, these energies are usually expressed in terms of wavenumbers (the reciprocal wavelength, expressed in centimetres, which is directly proportional to energy, and given the symbol cm^{-1}). All observed spectral features, in emission and absorption, are caused by changes in total energy, ΔE_T , of the individual species present within the flame. Spectral features arise from the emission or absorption of a photon with energy corresponding to the difference between initial and final states of the transition. **Figure 1** illustrates the absorption of a photon corresponding to an electronic transition (**Figure 1a**) and to a vibrational transition (**Figure 1b**) for a diatomic molecule whose interatomic potential energy may be approximated by an anharmonic oscillator.

In general, changes in electronic, vibrational, and rotational energy correspond to emission or absorption of radiation in the visible (and ultraviolet), infrared, and microwave region of the electromagnetic spectrum, respectively. Typically, $\Delta E_{EL} > \Delta E_{VIB} > \Delta E_{ROT}$. For molecular species, changes in E_{EL} generally are accompanied by changes in E_{VIB} and E_{ROT} , and changes in E_{VIB} may be (and almost are) accompanied by changes in E_{ROT} . These general trends are illustrated in **Figure 1**. The band structure observed in the visible and ultraviolet spectra of molecular species in flames, in emission and absorption, is therefore understood to be the result of combined changes in electronic, vibrational, and rotational energies.

The visible and ultraviolet radiation from most flames usually accounts for less than 1% of the total emitted

Figure 1 Potential energy diagram for a diatomic anharmonic oscillator. Electronic (a) and vibrational (b) absorption transitions are illustrated. Values for interatomic distance, energy (E), and term symbols are for the radical flame species CN.

energy, with most of the energy emitted by a flame occurring in the infrared region of the spectrum. To see why this is not unexpected, it is useful to compare the radiation emitted by a flame with the radiation emitted by a blackbody. In a system at thermodynamic equilibrium (which, on a macroscopic scale, a flame is not), the distribution of radiation is given by Planck's blackbody radiation law:

$$I_\lambda = [2E_\lambda c_1 \lambda^{-5} / (\exp[c_2/\lambda T] - 1)] A d\lambda \quad [2]$$

Here, I_λ is the wavelength-dependent radiant intensity normal to the surface of the radiator, E_λ is the emissivity at wavelength λ , c_1 and c_2 are the first and second radiation constants and have the values $0.588 \times 10^{-8} \text{ Wm}^{-2}$ and $1.438 \times 10^{-2} \text{ m K}^{-1}$, respectively, T is temperature in kelvin (K) and A is the area of the surface in square metres (m^2).

Figure 2 is a plot of eqn [2] at several temperatures. **Figure 2** shows that for a blackbody radiator, at temperatures up to 2300 K, the peak spectral radiance always occurs in the infrared region of the spectrum. As the temperature increases above 2300 K, the peak of spectral radiance moves to shorter wavelengths (towards the visible region of the spectrum). It is important to note that for a blackbody, the value of E_λ is equal to 1 at all

Figure 2 Radiation from an ideal blackbody at several temperatures.

wavelengths. In flames, the value of E_λ varies (and may approach 1) with wavelength, but is near zero for most wavelengths, indicating that a flame is not a blackbody, and that flame gases may not be in thermodynamic equilibrium. Nevertheless, in some cases where the emissivity of a flame species is known, measurements of spectral radiance of flames may be used to calculate flame temperatures to within an accuracy of several kelvin.

When the regions of non-zero emissivity ($E_\lambda > 0$) in the flame emission spectrum are expanded along the

wavelength scale, these regions exhibit detailed fine structure. In the visible and ultraviolet regions of the flame emission spectrum (in general, radiation with a wavelength between 1 μm and 200 nm), this fine structure represents changes in rotational and vibrational energy which accompany changes in electronic energy. In the more intense infrared region of the flame emission spectrum (in general, radiation with a wavelength between 1 and 30 μm), the observed fine structure is caused by transitions between rotational energy levels which occur with a change in vibrational energy, but with no change in electronic energy. The amount by which the vibrational and rotational energies may change during a transition is governed by selection rules, which are largely dependent upon the symmetry of the species involved in the transition.

Figure 3 shows the raw emission spectrum from a premixed, reduced pressure (18 torr) stoichiometric CH_4/O_2 flame measured using a Fourier transform infrared (FT-IR) spectrometer and the calculated emission from a blackbody at 1173 K over the same spectral region. The peak temperature in this flame was measured (using a fine wire Pt-Pt/10%Rh thermocouple) to be near 2150 K. Comparison of flame emission spectra to calculated blackbody radiance must take into account the emissivity of the different species within the flame, reabsorption of emitted radiation by cold gases outside of the flame region, emission from species at different temperatures along the line of sight of the measurement, chemiluminescence, and the variation in sensitivity of the instrument detector with wavelength. **Figure 3** illustrates that care must be taken when estimating flame temperatures from measured spectra, since results from simple fits of a blackbody radiation curve to a measured spectrum may be inaccurate.

Figure 3 The infrared emission spectrum measured using an FT-IR spectrometer from an 18 torr CH_4/O_2 flame and the blackbody radiation (1173 K) emitted over the same region. The infrared emission spectrum has not been corrected for the responsivity of the detector.

Background

Emission and absorption spectra of flames may be continuous or banded. Continuous emission spectra may be modelled using the Planck blackbody equation (eqn [2]). Modelling of banded spectra requires an understanding of the statistics that govern the way the population of a species is distributed among available energy levels. It is the dependence of population of molecular energy levels upon temperature, and the influence of this population upon band shape and spectral emissivity and absorption, which makes vibrational spectroscopy a useful tool for flame diagnostics.

The necessary mathematics for species and temperature measurements from infrared spectra of flames are outlined below. The example given is for a diatomic molecule, such as CO. It is assumed that the spectra are measured in absorption at low pressure, where the amount of light absorbed is less than approximately 5% of the incident intensity (often referred to as absorption in an optically thin medium). For extension to more complicated molecules (including more complicated diatomic molecules, such as NO), and to higher pressures, the reader should consult the 'Further Reading' section for details.

Population Distribution among Available Energy Levels

The classical Maxwell Boltzmann distribution law may be used to approximate the distribution of population among the quantized energy levels of a gas-phase diatomic molecule. For most diatomic molecules (such as CO, but not NO), each separate line shape observed in the infrared spectrum corresponds to a simultaneous change in vibrational and rotational energy. For this reason, the spectral lines that make up the band structure observed in most infrared spectra are often called rovibrational transitions. For purposes here, it is convenient to describe the initial and final energy levels of the transition as rovibrational energy levels.

When describing two energy levels of a given species, the superscript' denotes the state of higher energy, and the superscript'' denotes the state of lower energy. At thermodynamic equilibrium, the ratio of the number of molecules in the rovibrational energy level with vibrational quantum number v' and rotational quantum number J' to the number of molecules in the rovibrational energy level with vibrational quantum number v'' and rotational quantum number J'' is given by:

$$\frac{N_{J',v'}}{N_{J'',v''}} = \frac{(2J' + 1)}{(2J'' + 1)} \times \exp(-(\Delta E_v + \Delta E_J)/kT) \quad [3]$$

where $N_{J',v'}$ is the population of the higher rovibrational energy level, $N_{J'',v''}$ is the population of the lower rovibrational energy level, ΔE_v is the change in vibrational energy (units of cm^{-1}) and ΔE_J is the change in rotational energy (units of cm^{-1}) which occurs during the transition, h is Planck's constant, k is Boltzmann's constant, and c is the speed of light. The quantity $[(2J' + 1)/(2J'' + 1)]$ accounts for the degeneracy of rotational levels for a given value of J , providing a statistical weight to the levels with a given rotational energy.

For interpretation of measured spectra, it is useful to know the fraction of the total population (N_T) in the energy level from which the transition originates. For absorption (where the transition originates from the level of lower energy), this may be given by:

$$N_{J'',v''}/N_T = (N_{J'',v''}/N_{J=0,v=0}) / \left(\sum N_{J,v}/N_{J=0,v=0} \right) \quad [4]$$

where the summation is over all values of J'' and v'' and $N_{J=0,v=0}$ is the population in the rovibrational energy level with rotational quantum number J and vibrational quantum number v both equal to 0. The denominator on the right side of eqn [4] may be written to a first approximation as:

$$\sum N_{J,v}/N_{J=0,v=0} = \sum (2J + 1) \times \exp(-(E_v + BJ(J + 1))hc/kT) \quad [5]$$

The first rotational constant, B , is inversely proportional to the moment of inertia of the rotating molecule, and determines the rotational energy level spacing. This means that, in general, the larger the mass of the rotating molecule, the closer is the spacing of the rotational energy levels. The right-hand side of eqn [5] may be factored into rotational and vibrational components:

$$\sum N_{J'',v''}/N_{J=0,v=0} = Q_R Q_V \quad [6]$$

where Q_R and Q_V are, respectively, the rotational partition function and the vibrational partition function:

$$Q_R = \sum (2J'' + 1) \exp(-(B''J''(J'' + 1))hc/kT) \quad [7]$$

$$Q_V = \sum \exp(-(E_{v''})hc/kT) \quad [8]$$

The summations in eqns [7] and [8] are over all J and all v , respectively. Substituting eqns [3], [7], and [8] into eqn [4] gives:

$$N_{J'',v''}/N_T = (2J'' + 1) \times \exp(-(E_{v''} + B''J''(J'' + 1))hc/kT) / Q_R Q_V \quad [9]$$

Equation [9] shows how the fraction of total population in a given rovibrational energy level varies with temperature

and rotational and vibrational quantum numbers. For most gas-phase diatomic molecules, if the population in a known rovibrational level is measured, eqn [9] allows the total population (and hence total pressure) of the gas to be calculated.

Absorption of Radiation

The Einstein transition probability of absorption, B_{mn} (not to be confused with the first rotational constant B), predicts the energy removed (I_R) from an incident beam of radiation by an optically thin layer of absorbers for a transition from a lower state m to an upper state n as:

$$I_R = I_0 N_m B_{mn} \Delta x b v_{mn} \quad [10]$$

where N_m is the number of molecules per unit volume in the energy level from which absorptions occur, I_0 is the energy crossing unit area of absorbers per second, Δx is the absorber thickness, and v_{mn} is the energy (in cm^{-1}) of the monochromatic radiation exciting the transition. In eqn [10], $I_0 N_m B_{mn}$ is proportional to the number of transitions per second per unit volume produced by the radiation and $b v_{mn}$ is proportional to the energy removed from the incident beam per transition.

In an absorption experiment, the intensity of radiation exiting the absorbing medium, I , is described according to the Bouguer–Lambert Law (later restated by Beer for solutions):

$$I = I_0 \exp(-\sigma(\lambda) N_m x) \quad [11]$$

where x is the pathlength travelled by the light through the absorbing medium, and $\sigma(\lambda)$ is called the cross section for absorption. This cross section represents the 'effective area' that a molecule presents to the incident photons. When $\sigma(\lambda) N_m x$ is small (optically thin medium), eqn [11] may be rewritten:

$$I_0 - I = I_0 (\sigma(\lambda) N_m x) \quad [12]$$

Integrating eqn [12] over the wavelength range for which the absorption may occur gives:

$$\int (I_0(\lambda) - I(\lambda)) d\lambda = \int I_0(\lambda) (\sigma(\lambda) N_m x) d\lambda \quad [13]$$

The way in which the cross section for absorption ($\sigma(\lambda)$) varies with wavelength depends mainly upon the total pressure of the gas. For gas pressures above approximately 100 torr, the absorption is observed to occur with a Lorentzian line shape given by:

$$\sigma(\lambda) N_m x = 2.303 A_0 \gamma^2 / ((c/\lambda - c/\lambda_0)^2 + \gamma^2) \quad [14]$$

where A_0 is the peak spectral absorbance ($-\log(I(\lambda)/I_0(\lambda))$) at the wavelength of maximum light attenuation

by the gas, and γ is the half width at half height (HWHH) of the spectral line.

Substituting eqn [14] into eqn [13], assuming that I_0 is invariant with wavelength over the absorption line width, and integrating over the full line width gives:

$$\begin{aligned} & \int (I_0(\lambda) - I(\lambda)) d\lambda \\ &= 2.303 I_0(\lambda) \int A_0 \gamma^2 / ((c/\lambda - c/\lambda_0)^2 + \gamma^2) d\lambda \\ &= 2.303 I_0(\lambda) \pi A_0 \gamma \end{aligned} \quad [15]$$

Substituting eqn [15] into eqn [10], and solving for the peak absorbance, A_0 , gives

$$A_0 = N_m \Delta x \times B_{mn} b \nu_{mn} / 2.303 \pi \gamma \quad [16]$$

The number of molecules in the initial state, N_m is related to the total number of molecules, N_T , through the vibrational (Q_V) and rotational (Q_R) partition functions:

$$\begin{aligned} N_m &= N_T (2J'' + 1) \\ &\times \exp(-(E_{v''} + B'' J''(J'' + 1))hc/kT) / Q_R Q_V \end{aligned} \quad [17]$$

Substituting eqn [17] into eqn [16] gives:

$$\begin{aligned} A_0 &= [\Delta x B_{mn} b \nu_{mn} N_T (2J'' + 1) / 2.303 \pi \gamma Q_R Q_V] \\ &\times \exp(-(E_{v''} + B'' J''(J'' + 1))hc/kT) \end{aligned} \quad [18]$$

Equation [18] is useful for extracting temperature and concentration information from measured values of peak absorbance (A_0) for individual transitions in a rovibrational band. By simultaneously fitting T and N_T to A_0 measured over a rovibrational band, temperature and gas pressure may be obtained. Equation [18] shows that it is necessary to know the half width at half height (HWHH) of each line in the spectrum used in the calculation, and the value of B_{mn} . This is not always trivial, since this value may be temperature and J -value dependent. Additionally, it is important to recognize peak absorbances must be corrected when measured with an instrument of moderate spectral resolution. The method for extracting true peak absorbance from peak absorbance measured at moderate resolution has been treated in detail by Anderson and Griffiths. Substituting eqn [18] into eqn [16], and expressing the result in the form of the Bouguer–Lambert Law gives:

$$\begin{aligned} I(\lambda)/I_0(\lambda) &= \exp[(-\Delta x B_{mn} b \nu_{mn}(\lambda) N_T \gamma / \pi Q_R Q_V \\ &\times (c/\lambda - c/\lambda_0)^2 + \gamma^2)(2J'' + 1) \\ &\times \exp(-(E_{v''} + B'' J''(J'' + 1))hc/kT)] \end{aligned} \quad [19]$$

Equation [19] allows direct comparison between high resolution measurements of transmittance ($I(\lambda)/I_0(\lambda)$)

Figure 4 Calculated transmittance of light through a fixed pressure of CO gas at different temperatures. Spectra are offset for clarity (each baseline corresponds to 100% transmission).

and transmittance calculated from spectral parameters, pressure of the absorbing gas, and the temperature. It should be noted that knowledge of the spectral line HWHH (γ) is required, as well as an instrument capable of measuring the transmittance at high resolution. In practice, values of B_{mn} (usually converted to line strengths) for different rovibrational transitions are taken from the literature or estimated from measurements of total band strength. Also, the Voigt line shape profile, which describes the convolution of a Gaussian line shape function (applicable to gases at low pressure) and a Lorentzian line shape function, is usually used to model spectral lines in flames at reduced pressure. As with fits to data based upon eqn [18], when spectra are measured on an instrument of moderate resolution (in general, an instrument resolution $> 0.1\gamma$), the instrument line shape function is convoluted with the true line shape (eqn [19]). When this is the case, this convolution must be included in the model.

Equation [19] describes the fully resolved band structure observed in high resolution infrared spectra of many gas-phase diatomic molecules, such as CO. **Figure 4** shows the transmittance ($I(\lambda)/I_0(\lambda)$) spectrum of CO, calculated using eqn [19], for a constant number of molecules at the temperatures shown in **Figure 2**. **Figure 4** shows that as the temperature increases, and more rotational energy levels becomes populated, the overall shape of the absorption band broadens to cover a wider spectral range. Additionally, because the total number of molecules is divided between a greater number of initial energy levels as temperature is increased, the intensity of individual rovibrational transitions changes with increasing temperature.

Experimental Methods Narrative

By the 1950s, the mathematical and instrumental methods for determination of temperatures and species

concentration from measurements of infrared spectra had been established, in large part spurred by electronics developed during the Second World War, by perfection of the method of commercial replication of diffraction gratings, and by publication in 1945 of Hertberg's book *Infrared and Raman Spectra of Polyatomic Molecules*. During the 1950s, comparison of infrared emission spectra from high temperature sources in different laboratories was complicated by temperature gradients along the measurement line of sight, and by incomplete spectral parameters for gas absorption at high temperatures. To obtain spectral parameters for gases under study, several efforts were made to study gases in closed cells at controlled temperatures. Most of these efforts at studying gases at high temperature under static conditions employed absorption spectroscopy, in part to minimize self-absorption along the line of sight, and also to enable using modulation of the source radiation (allowing discrimination of the high intensity, unmodulated background infrared emission). The success in fundamental studies of band structure and in predicting emissivities and changes in absorption at high temperatures and pressures led to an increase, by the early 1960s, in studies of radiation transfer for systems ranging from jet and rocket motors to high efficiency oil burners. A particular success which resulted from the study of gas-phase emissivities was the determination of thermal stress on NASA rocket motors from exhaust gas radiation.

With the development in the early 1970s of the Fourier transform spectrometer and the computer-based fast Fourier transform (FFT), it became possible to achieve high resolution coupled with high energy throughput and phase-sensitive detection. However, the development of laser-based techniques (particularly laser-induced fluorescence (LIF) for measurement of flame radical species, such as OH, HCO, H, O, CH, and C₂) enabling direct measurement of species participating in flame propagation reactions caused a shift in focus of fundamental spectroscopic investigations of flame systems. This shift led to a decrease in the late 1960s and early 1970s in the number of publications describing basic research that applied the techniques of dispersive infrared absorption and emission spectroscopy to flames. This decrease was offset by a considerable body of work on emission studies of hot gas sources, particularly smokestack and waste gas plumes from industrial sources.

By the late 1970s, laser-based techniques employing tunable infrared lasers began to be used for species measurements in flames. The majority of this work used tunable diode lasers (TDLs), semiconductor devices in which the output laser radiation wavelength is tuned by varying the temperature and diode injection current. Initial experiments used TDLs emitting narrow line-width (typically $<10^{-4}\text{ cm}^{-1}$) radiation in the mid-infrared spectral region. The narrow line width usually

enables species specificity, even in congested spectral regions. Since the laser line width is typically several orders of magnitude less than the absorption line width, measurements of the fully resolved absorption transition may be made, enabling the determination of line shape dependence upon pressure and temperature. An additional advantage to using tunable diode lasers, besides very narrow line widths, is the ability to tune the lasers, rapidly (kHz to MHz) over their output wavelength range. This enables phase-sensitive detection that minimizes the effect of the laser output noise, and also enables time-resolved measurements of dynamic systems.

More recently, tunable diode lasers operating in the near-infrared spectral region began to see application to the spectroscopy of flames and to flame gases. At this time, commercial availability of TDLs in the mid-infrared spectral range is greater than for the near-infrared spectral range. TDLs operating in the mid-infrared spectral range must be cooled to cryogenic temperatures. TDLs operating in the near-infrared spectral range operate near room temperature, and unlike mid-infrared radiation, the near-infrared radiation may be transmitted over long distances through optical fibres. However, since absorption in the near-infrared spectral region corresponds to a change in vibrational quantum number greater than unity (referred to as an overtone transition), the sensitivity to a given molecule is much less than for mid-infrared spectroscopy, which is usually used to measure rovibrational transitions in the fundamental vibrational band. Typically, mid-infrared TDLs are used when extreme sensitivity is required (ppb range). For many field-based techniques which require transportability in rugged environments, near-infrared TDLs are more appropriate (ppm range).

Experimental Methods – Dispersive and Fourier Transform Spectroscopy

Emission Measurements

Since the mid-1970s, most measurements of emission spectra of steady flames have used Fourier transform techniques. **Figure 5** shows the emission spectrum measured from a premixed, stoichiometric CH₄/O₂ flame (total pressure equal to 18 torr) to which 3% CF₃Br has been added as a flame suppressant. When appropriate, reduced-pressure flames are often studied because at reduced pressure the flame region is expanded, allowing more detailed study. The emission spectrum shown in **Figure 5** was measured using a Fourier transform infrared (FT-IR) spectrometer at a resolution of 1 cm^{-1} .

In **Figure 5**, spectral features from several flame species are identified, but the spectrum is dominated by emission from CO₂ and gaseous H₂O. This is because higher temperatures allow emission over a wide range of

Figure 5 The infrared emission spectrum measured from a premixed, stoichiometric CH_4/O_2 flame (total pressure 17 torr) to which 3% CF_3Br has been added.

rovibrational transitions (see **Figure 4**), from combinations of different vibrational states, and the geometry of the emitting species (specifically in this case H_2O) causes the spectrum to be complicated (relative to that for a diatomic molecule). The measured spectrum in **Figure 5** reports emission from species over a wide range of temperatures, because the line of sight from the flame centre to the detector includes gases at many different temperatures. Also, because many flame species are products of an ongoing chemical reaction (combustion), these species may be produced with vibrational and rotational population distributions which are not in equilibrium with translational temperatures. Because of this, temperatures calculated from emission spectra using expressions similar to eqn [18] or [19] may give misleading results. When these factors are taken into account, temperature and partial pressures of gas species may be extracted from high resolution measurements of infrared emission spectra.

Absorption Measurements

Figure 6 shows an absorption spectrum measured through an opposed-flow CH_4/air flame (total pressure 50 torr) using an FT-IR spectrometer at 1 cm^{-1} resolution. It should be noted that this spectrum is less congested and has a slightly more regular appearance than that shown in **Figure 5**. Absorption features from several species are evident in the spectrum. For flame diagnostics using infrared absorption spectroscopy, CO is probably the most widely studied molecule. The fundamental rovibrational absorption band of CO ($\nu = 0-1$, centred at 2170 cm^{-1}) is well approximated by eqn [19], and has a spacing between rotational lines (2B) of approximately 3.6 cm^{-1} . Modelling of measured spectra is

Figure 6 The infrared absorption spectrum measured through a 50 torr opposed-flow CH_4/air flame. The inset shows the burner configuration used to produce the flame.

Figure 7 The transmittance spectrum of the first overtone ($\nu = 0-2$) of CO. The gas was contained in a static cell at 1 atmosphere total pressure and a temperature of 423 K. The dotted line is the measured spectrum; the solid line represents the least-squares fit to the data.

relatively straightforward and fully resolved rovibrational lines may be measured at moderate instrument resolution (although the reported line shape may be just the instrument line shape function). In addition, since CO is a major product of hydrocarbon combustion, it is present in most flame systems. **Figure 7** shows the spectrum of the first overtone ($\nu = 0-2$) of CO, measured using a dispersive system, and the fit to the measured spectrum using an equation similar to eqn [19]. Since the resolution of the spectrometer used to measure the spectrum in **Figure 7** was insufficient to fully resolve the line shapes of the individual rovibrational transitions, it was necessary to convolute the instrument function with the true line shape function (eqn [19]) to obtain an accurate fit of the measured to the calculated spectrum.

A major difficulty in obtaining quantitative absorption measurements of flame species is that absorption of radiation by cold gases in the probe beam line of sight may lead to errors. Currently, several methods of

Figure 8 Experimental apparatus for measurement of FT-IR absorption spectra through flames. The system is designed to minimize the amount of flame emission which reaches the interferometer. The burner is mounted on a translating stage (X and Z axes) to allow for tomographic analysis.

excluding contributions to absorptions by cold gases in the line of sight are used, with most methods employing some type of computer averaged tomography (CAT). Using these methods (often referred to as inversion methods), multiple line of sight measurements at different relative orientations are made within a plane, or slice, through the flame. Using these multiple line of sight measurements, numerical methods are used to calculate species concentration at a given point within the plane. Applying this technique to multiple planes, or slices through the flame, can yield a three-dimensional reconstruction of species concentration within the flame. This technique has been used to measure CO in reduced- and atmospheric-pressure flames. A summation of inversion methods used to measure temperatures and species in flames has been given by Limbaugh.

It should be noted that when measuring flame absorption spectra using an FT-IR spectrometer, care must be exercised so that flame emission is not reflected through the interferometer and reported as an absorption signal. To minimize the emitted radiation which reaches the interferometer, the collimated probe infrared beam is brought to a focus at an iris prior to entering the flame region. After passing through the iris, the probe radiation is re-collimated prior to entering the flame. While useful for identification of species within the flame, FT-IR spectroscopy will not yield high spatial resolution unless the infrared probe beam is reduced in cross section (usually by being passed through a set of apertures) prior to entering the flame region. This reduction in power of the infrared probe beam energy reduces the signal to

noise ratio in the measured spectrum. A typical experimental setup for measuring infrared absorption spectra through a flame using an FT-IR spectrometer is shown in **Figure 8**.

Most commercial spectrometer systems employing broadband sources (typically FT-IR systems) are not capable of resolving the true line shape of an absorbing gas-phase species because of limitations to instrument resolution. The instrument yields the convolution of the true absorbing gas line shape and the instrument response function. Computer-based programs used to retrieve species concentration and temperature must either take into account this convolution, or use for calculations the instrument response-corrected peak intensity of the rovibrational transition.

Experimental Methods – Applications of Tunable Diode Laser Absorption Spectroscopy (TDLAS)

Tunable diode lasers (TDLs) are semiconductor devices (typically GaAs) which are essentially light-emitting diodes constructed with an optical resonator. Lasing is achieved by delivering a small current to the photodiode. Tuning is achieved by changing the temperature, and hence the Fermi level, of the device. The tuning range varies by type, but is usually between 2 cm^{-1} and 30 cm^{-1} . The useful tuning range (that is, the range over which the device may be rapidly tuned without encountering changes in laser modes, which can mask

absorption features) is usually less than 1 cm^{-1} . This restricted tuning range means that the devices are not used in a survey mode. In general, a TDL laser spectrometer system is designed to detect a single gas using a single, specially fabricated, dedicated, laser diode. Occasionally, absorption transitions from different gases of interest may occur within the useful tuning range of a single laser, but such occurrences are usually fortuitous. Additionally, because of the limited tuning range, calculation of temperature and species concentration may be difficult when only one line is measured.

There are, however, several advantages to using TDLs for measurement of gas-phase flame species. These include high resolution (typically better than $1 \times 10^{-4}\text{ cm}^{-1}$), good spatial resolution (200 to 1 mm), reasonable output power ($\sim 1\text{ mW}$), and the ability to scan over their spectral range on a millisecond or better timescale. Probably the most widely studied molecular flame species by tunable diode laser spectroscopy is CO. In addition to the reasons for study outlined above in the discussion of broadband source methods, CO possesses several fundamental ($v = 0-1$) and hot-band transitions ($v = 1-2$, $v = 2-3$) which occur within several line widths (approximately 0.05 cm^{-1}) of each other. At room temperature, populations of states from which hot-band transitions occur are very low. However, at flame temperatures, populations of vibrational states other than the $v = 0$ state may become appreciable. When temperatures (and also species concentrations) are calculated from simultaneous measurement of a fundamental and a hot-band transition, the technique is referred to as two-line thermometry.

Figure 9 shows several spectra of CO measured in a low-pressure (20 torr), stoichiometric CH_4/O_2 flame using mid-infrared tunable diode laser spectroscopy. Because the wavelength of the diode laser radiation

Figure 9 Mid-infrared tunable diode laser spectra of CO, measured through a premixed CH_4/O_2 flame, at a total pressure of 20 torr, as a function of height above the burner surface. The maximum temperature calculated using two-line thermometry was 2150 K.

corresponds to single quantum number changes in CO (in this case a $v = 0-1$ and a $v = 1-2$ transition) simple absorption spectroscopy may be employed. Each spectrum is measured at a different height above the burner surface. For these experiments, the probe laser beam location was fixed, and the burner location was translated vertically. The infrared laser beam diameter through the flame region was 0.5 mm. As the diode laser radiation passes through different portions of the flame, the relative areas under the two peaks correspond to absorption from different rovibrational levels changes. Figure 10 shows the results of fitting an equation similar to eqn [19] to an absorption spectrum from Figure 9. Using this method, the CO vibrational temperature was calculated as a function of height above the burner surface ($T_{\text{max}} = 2150\text{ K} \pm 50\text{ K}$). Additionally, tomographic analysis of the data showed that the error from cold gas absorption, for these experiments, was always less than 10% of calculated temperatures and partial pressures.

Tunable diode laser spectroscopy is also used for detection of many trace gas species in flames and in flame environments. The method used for measurements of small amounts of gases (often to the ppb range) relies on modulation spectroscopy using phase-sensitive detection. The principal advantage to using modulation spectroscopy results from minimization of laser output noise by shifting detection to high frequencies. When phase-sensitive detection is employed using tunable diode lasers, the second derivative of the diode laser probe beam intensity with respect to wavelength is usually measured, since the wavelength at which the second derivative is a maximum coincides with the wavelength of maximum light absorption. The second-derivative signal

Figure 10 A transmission spectrum measured through a low-pressure, premixed, CH_4/O_2 flame at 20 torr. The main absorption features are the two CO lines used to calculate temperature using the method of two-line thermometry. Calculated temperature was 2150 K.

peak height may be shown to be proportional to absorbance, A :

$$X''/V = kA \quad [20]$$

Here, X'' is the peak height of the second-derivative signal (volts), V is the DC voltage measured by the detector in the absence of any molecular absorbance, and k is a constant which includes the measuring instrument and optics function. Letting S , denoted as the $2f$ signal peak to trough height the distance between the maximum and minimum points on the $2f$ signal – see Figure 11c), equal X''/V , yields:

$$S = (k\alpha)LP \quad [21]$$

The slope of a plot of LP versus S provides the value of $k\alpha$. A calibration of the system using known concentrations of the absorbing gas must be performed to determine the value of $k\alpha$. Once this value is known, gas pressure (P) may be obtained directly from eqn [21]. Care must be exercised so that changes in optical surfaces during measurement (as when measuring corrosive gases such as HF) do not affect the value of $k\alpha$, since this value is instrument-function dependent. For this reason, calibration should be performed at the beginning and end of each measurement set. Additionally, for gas concentrations which attenuate more than 5% of the incident light, the linear relationship between gas pressure and $2f$ signal peak height may no longer hold.

Modulation spectroscopy using tunable diode lasers (often referred to as $2f$ spectroscopy) has been extensively discussed in the literature. Figure 11 gives a generic description of the signal processing employed in these experiments. Briefly, the laser output wavelength is

Figure 11 Simulated signal versus wavelength of laser radiation after passing through a gas with an absorption feature near 7665.5 cm^{-1} . Graphs for (a) unmodulated laser radiation; (b) laser radiation with a small-amplitude, high-frequency modulation; (c) demodulation at twice the high-frequency modulation in (b).

scanned (10 Hz–10 kHz) through a spectral region where the gas being measured absorbs. The output at the detector during the laser scan (with the high-frequency modulation turned off) may be seen in Figure 11a. A high-frequency (10 kHz to MHz) wavelength modulation with an amplitude approximately equal to the line width under investigation is superimposed on the laser drive current (Figure 11b). Demodulation at twice the frequency of the high-frequency laser drive modulation yields the second-derivative signal shown in Figure 11c. It should be noted that Figure 11a shows that the laser diode output power has a non-linear dependence on laser drive current. While this is non-ideal behaviour, this is a common trait of commercially available laser diodes. The non-linear power output dependence on laser drive current (exaggerated here for illustration) causes the sloping baseline for the second-derivative signal in Figure 11. For measurements at extremely low concentrations or for gases with small absorption cross sections, the non-linearity of laser diode output power with laser drive current may affect limits of detection.

Modulation spectroscopy enables discrimination against contributions to light attenuation by scattering from particulate matter using a single laser beam. Attenuation of laser radiation by a rovibrational transition of a small gas molecule is detected because the wavelength range of the scan is several times the width of the spectral absorption feature (typically on the order of 0.1 cm^{-1} at atmospheric pressure). Because light scattering by particulate matter is nearly constant over the very small wavelength range of the laser scan, the change in detector signal intensity with the change in wavelength is effectively zero in the absence of any absorbing gas. However, because the $2f$ signal is also proportional to the background signal intensity, the second-derivative signal is divided by the DC signal to account for light scattering by particles.

While modulation techniques enable trace gas detection, special care must be exercised when making measurements in flames, especially when using near-infrared laser radiation. Significant errors in measured concentrations may arise because of beam steering as the laser radiation passes through the flame. In some cases, the beam steering may be severe enough to cause loss of signal at the detector. Secondly, great care must be exercised when measuring $2f$ spectra through regions of differing temperature and pressure, since the $2f$ signal is extremely sensitive to changes in line width of the absorbing species.

Conclusion

Infrared spectroscopy continues to be a valuable tool for measuring species concentrations and temperatures in

flames and combustion gases, especially in field-based studies. The advent of compact, fibre-coupled, tunable diode lasers operating at room temperatures is expanding the use of vibrational spectroscopy beyond the laboratory, and providing a useful complement to broadband methods currently in place.

This article gives an overview of the current applications of the technique of fluorescence microscopy. The four sections describe, respectively, (1) the basic principles of fluorescence microscopy, (2) the types of information which can be obtained by fluorescence microscopy, (3) the technical ways in which fluorescence microscopy can be adapted to study various chemical species and (4) some examples of the range of biological, mineralogical and artificial specimens that can be studied.

Principles of Fluorescence Microscopy

Fluorescence microscopy is a technique whereby fluorescent substances are examined in a microscope. It has a number of advantages over other forms of microscopy, offering high sensitivity and specificity.

In fluorescence microscopy, the specimen is illuminated (excited) with light of a relatively short wavelength, usually blue or ultraviolet (UV). The specimen is examined through a barrier filter that absorbs the short-wavelength light used for illumination and transmits the fluorescence, which is therefore seen as bright against a dark background (**Figure 1**). Because fluorescence is observed as luminosity on a dark background, fluorescent constituents of the specimen can be seen even in extremely small amounts. There are several different modes of fluorescence microscopy, of which the most important is confocal fluorescence microscopy.

In most modern fluorescence microscopes, epi-illumination is employed. This means that the light used for excitation is reflected onto the specimen through the objective, which acts as a condenser. Opaque or very thick objects can be examined using epi-illumination, even the skin of living people.

The position of fluorescence microscopy in relation to other techniques is summarized in **Table 1**. Conventional, transmitted-light, absorption microscopy is appropriate for coloured objects of resolvable size, and instrumentally is the simplest form of microscopy.

Colourless, transparent objects can be studied only by retardation techniques (polarization, phase-contrast, interference); these techniques depend upon conversion of phase retardation into changes in intensity that can be seen by the eye. An exception is darkground illumination, which may reveal colourless transparent objects by reflection or refraction at interfaces of differing refractive indices. Darkground microscopy is otherwise suitable mainly for particulate matter, and (like fluorescence microscopy) can reveal the positions of particles too small to be resolved. Fluorescence microscopy is closely allied to transmission (absorption) microscopy in its range of application, but possesses particular advantages:

Figure 1 Fluorescence photomicrographs of a section of a plant stem, cut longitudinally (main picture) and transversely (inset, at higher magnification). The tissue was stained with a fluorochrome, Aniline blue, to show the sugar-conducting tissue (phloem). Aniline blue stains specialized regions of the cell walls. Intense fluorescence is most obvious on the transverse (end) walls of elongated cells. The end walls have pores so that there is continuity from cell to cell, forming a continuous tube in which sugars may be moved down the plant from the leaves. A face view of one of the end walls is shown in the inset. There is a ring of fluorescence around each pore. There is also fluorescent staining, to a much lesser degree, on the longitudinal walls. This surrounds pores that allow sugar transport between adjacent tubes. Aniline blue stains $1 \rightarrow 3\beta$ -glucans. Here it is staining callose, a glucan which is deposited to occlude the pores should the tubes become damaged, as when tissue is cut. This presumably blocks the cut part of the tubes, minimizing loss of sugars from the cut ends of the tubes, and may well also minimize entry of microorganisms that would be attracted by leaking sugars. The tubes shown in the main picture are $70\text{ }\mu\text{m}$ in diameter. Field size of main picture approximately $500 \times 1000\text{ }\mu\text{m}$ ($0.5 \times 1\text{ mm}$), of inset approximately $100 \times 100\text{ }\mu\text{m}$. Table 1 Applicability of fluorescence microscopy, compared with other techniques

<i>Specimen</i>	<i>Fluorescence</i>	<i>Type of microscopy</i>		
		<i>Absorption (transmission)</i>	<i>Retardation (DIC, Pol, etc.)</i>	<i>Reflection (incl. darkground)</i>
Coloured	Suitable	Suitable	Unsuitable	Suitable
Transparent	Impossible	Impossible	Suitable	Impossible
Opaque	Suitable	Impossible	Suitable	Suitable
Dynamic	Suitable	Impossible	Impossible	Impossible
Particles below limit of resolution	Suitable	Impossible	Unsuitable	Suitable

Absorption microscopy is the conventional transmitted-light type. Retardation microscopy includes Nomarski interference-contrast (DIC), phase-contrast and polarization. Reflection microscopy includes darkground.

great sensitivity for detection and quantification of small amounts of fluorescent substances or small particles, and the possibility of application to opaque objects. Since fluorescence involves two wavelength bands (excitation and emission), optical specificity can be substantially increased by careful selection of filter combinations to favour the excitation and emission of some particular fluorophore, and modern developments also permit time-resolution of the fluorescence lifetime.

Fluorescence microscopy, because of its complexity, gives more difficulty than usual in interpretation of the image. Factors which may affect the appearance of the image in a fluorescence microscope are related to the specimen, to the microscope optical system (particularly the filter combination) and to the observer's own optical and neurological characteristics. In particular, the use of a narrow-band barrier filter can be misleading, since it makes everything appear its specific colour, whereas a wide-band or long (wavelength)-pass filter allows differentiation of different colours. Even photography, apparently objective, may be misleading if not interpreted correctly.

The current definitive texts on fluorescence microscopy are those of Rost (see Further Reading). There also exist several introductory works, such as that of Abramowicz, and a vast specialized literature. The major texts on confocal fluorescence microscopy are those of Pawley and of Wilson.

Types of Information to Be Obtained

Because many substances are fluorescent, or can be made so, fluorescence microscopy is widely applicable. It has a number of advantages over other forms of microscopy, offering high sensitivity and specificity. Because fluorescence is observed as luminosity on a dark background, specific constituents of the specimen can be seen even in minute amounts. Therefore, fluorescence microscopy is used mainly to detect and localize very small amounts of substances in specimens. The chemical substance being studied is either fluorescent of itself, made so by a chemical process or attached to a fluorescent label.

Fluorescence microscopy offers three significant capabilities. First, its high sensitivity allows very low concentrations of specific substances to be localized. Second, specific substances can be localized in structures smaller than the resolution of the microscope. Third, fluorescence is particularly suitable for confocal microscopy, which offers optical sectioning, giving very clear imaging and the possibility of building up 3D reconstructions.

As in other forms of microscopy, there are three basic kinds of fluorescence microscopy: qualitative, quantitative and analytical. Qualitative fluorescence microscopy is concerned with morphology, or with whether something (e.g. an immunological reaction) is present. Quantitative fluorescence microscopy is concerned with finding out how much of a specific substance is present in a specified region of the specimen. Analytical fluorescence microscopy is the characterization of a fluorophore by measurement of excitation and emission spectra or other characteristics such as polarization or decay time. Kinetic studies essentially involve studying the fluorescence parameters described above over a period of time; examples include the study of fading rates, enzyme kinetics, time-resolved fluorescence and phosphorescence.

Photomicrography

Images may be captured by film photography or, more commonly nowadays, by digital means. Film photography is best achieved by fast colour-positive (transparency) film in a small (35 mm) format. However, film has been largely replaced by solid-state electronic devices (e.g. CCDs) because of their higher quantum efficiency, enabling the recording of fluorescence which is weaker or the use of a shorter exposure time, together with the convenience of digital data. Confocal microscopy produces a digital image directly.

Video Intensification Microscopy (Analogue and Digitized)

Attachment of a video camera to a fluorescence microscope facilitates viewing of the image, which is normally

rather dim. A video camera, particularly one using a CCD, can readily be interfaced to a computer for image analysis. For details of video microscopy, see the book by Inoué and Spring and for an introduction to technique see the book by Herman, both listed under Further Reading.

Confocal Fluorescence Microscopy and 3D Imaging

If both the illumination and detection systems are simultaneously focused onto a spot which is scanned over the specimen, this is called confocal fluorescence microscopy, and has several advantages. Most importantly, the confocal microscope has sharp depth discrimination, and therefore produces optical sections in the plane of focus. This is because the detector does not accept all the light from out-of-focus planes and so these are imaged less strongly than the in-focus plane. Background fluorescence is thereby sharply reduced. Three-dimensional data can be obtained by computer reconstruction of a series of optical sections. Confocal fluorescence microscopy offers greatly increased discrimination against background and some increase in resolution, and gives the possibility of optical sectioning and three-dimensional reconstruction. For detailed information, see the books by Gu, Matsumoto, Pawley, and Wilson listed under Further Reading.

Other Modes

Several other modes of fluorescence microscopy have been developed, including automated fluorescence image cytometry (AFIC), fluorescence resonance energy transfer microscopy (FRET), two-photon fluorescence microscopy, total internal reflection fluorescence microscopy, and standing-wave fluorescence microscopy.

Combination with Other Techniques

Because the image seen in the microscope may consist of only a few small fluorescent areas in an otherwise black field, fluorescence microscopy is sometimes supplemented with other forms of microscopy to enable the specimen as a whole to be visualized and to show the position of fluorescent areas in relation to the rest of the specimen. Fluorescence microscopy is easily combined simultaneously or alternately with other methods for increasing object contrast, such as darkground illumination, interference-contrast (DIC) or phase-contrast microscopy. Combined electron microscopy and fluorescence microscopy of the same stain is possible with a small number of stains which contain heavy atoms.

Quantification by Microfluorometry

For quantification, microfluorometry has four advantages as compared with microdensitometric methods: distributional error does not occur, so that scanning or two-wavelength techniques are not required; optical specificity can be obtained by selection of appropriate wavelengths both for excitation and for measurement of emission; great sensitivity can be obtained; and thick or opaque objects can be examined. Disadvantages of microfluorometry include the necessity for artificial standards, and (usually) relatively rapid fading of the specimen. It is important to ensure that the background fluorescence is kept to a minimum and that an adequate standard is available.

Microspectrofluorometry

Excitation and/or emission spectra are measured from a specified area of the specimen using a microspectrofluorometer. Such instruments usually have to be assembled by addition of an appropriate light source and monochromators to a microfluorometer. This can be applied either for the identification of unknown fluorophores or to the investigation of the conditions of fluorescence of known fluorophores. The main application to date has been the identification of neurotransmitter amines *in situ* using formaldehyde-induced fluorescence.

Kinetic Studies: Time-Related and Video Fluorescence Microscopy

Kinetic studies essentially involve studying the fluorescence parameters described above over a period of time; examples include the study of fading rates, enzyme kinetics, time-resolved fluorescence and phosphorescence.

Scanning of the image with a television camera, with the televised image shown on a video monitor, enables an otherwise dim image to be seen more conveniently. Time-lapse video recording can be used to study movements of fluorescent probes in living cells.

The specimen often photobleaches (fades) under irradiation. Photobleaching is put to good use in modern studies of molecular kinetics using video recording and subsequent measurements of fluorescence recovery after photobleaching (FRAP), which gives information about rates of diffusion of fluorescent species back into a bleached area.

Fluorescence Lifetime Imaging Microscopy (FLIM)

In this technique, the instrumentation provides time resolution of the fluorescence process, enabling spatial resolution of changes in fluorescence lifetime caused by

environmental changes. This is useful for monitoring intracellular processes which cannot be studied by other means.

Types of Fluorescence

Autofluorescence

Autofluorescence (primary fluorescence) is the fluorescence of naturally occurring substances, such as chlorophyll, collagen and fluorite. Most plant and animal tissues show some autofluorescence when excited with ultraviolet light (e.g. light of wavelength around 365 nm). Sometimes this autofluorescence is a nuisance as it may conceal or be confused with a specific fluorescence. The term autofluorescence is sometimes extended to cover the fluorescence of drugs and other exogenous substances which may be present in tissues, e.g. tetracycline antibiotics which accumulate in growing bone. In biology, autofluorescence is often regarded as a nuisance, masking the specific fluorescence of introduced substances, but it usually provides a guide to the morphology of the tissue, and is also worthy of study in its own right. In geology, fluorescence microscopy is widely used to study coal. In minerals, autofluorescence is most commonly due to the presence of trace amounts of activator substances, generally regarded as 'impurities'.

Induced Fluorescence

This is observed following a chemical reaction to convert some non-fluorescent substance, already present in tissue, into a fluorescent substance. The most important example is the demonstration of neurotransmitter amines such as noradrenaline, which can be converted into fluorescent substances by treatment with formaldehyde or glutaraldehyde.

Fluorochromy

This is the process in which specimens are stained with fluorescent dyes, as compared with diachromy in which tissues are stained with coloured dyes. An example is shown in **Figure 1**, in which structures in a botanical specimen are stained with a fluorescent dye, Aniline blue. Many dyes which are used as coloured stains are also fluorescent, and can be used as either diachromes or fluorochromes. Hence, many conventionally stained preparations can be examined with either a conventional microscope or a fluorescence microscope. However, the use of fluorescence microscopy extends the range of dyes which can be used, because of the additional possibility of using dyes which are colourless or nearly so but fluoresce in the visible region after excitation with ultraviolet light. Fluorescence also gives increased sensitivity. Staining can also be carried out after chemical treatment, as in the

Table 2 Some examples of fluorochromes (fluorescent stains)

<i>Field</i>	<i>Application</i>	<i>Stain</i>
Bacteriology	Acid-fast bacteria	Auramine O
Botany	Plant cell walls	Calcofluor White
Cell biology	Chromosome banding	Quinacrine, Quinacrine mustard
Cell biology	Labels for affinity reactions	FITC, Texas Red isothiocyanate
Cell biology	Membrane lipids	ANS, SITS
Cell biology	Nucleic acids	Acridine Orange, bisbenzimidazole
Neurology	Nerve cell tracing	Dil
Pathology	Amyloid	Thioflavine T

Schiff reaction for carbohydrates and in the Feulgen reaction for nucleic acids. Some staining procedures commonly applied to biological material are listed in **Table 2**. For data and references on fluorochromes and fluorescent probes, see the Molecular Probes Handbook and the books by Kasten, Mason and Rost.

Immunofluorescence

This is a special form of fluorochromy, in which the site of an antigen-antibody reaction is revealed by labelling one of the components of the reaction (the antigen, the antibody or complement) with a fluorescent dye. Such reactions allow specific proteins to be localized rapidly, reasonably accurately and with great sensitivity.

Similar techniques are used for the demonstration of other cytochemical affinity reactions, such as in nucleic acid hybridization and in the binding of lectins, hormones and other substances. These techniques are termed indirect fluorochromy, since the fluorochrome is bound indirectly (through at least one intermediate molecule) to the substrate (the substance intended to be stained). Immunofluorescence, nucleic acid hybridization and similar affinity reactions have made an enormous contribution to cell biology.

Double- and triple-staining techniques enable visualization of two or more affinity reactions in the same preparation, using differently coloured fluorochromes for each reaction. Special filter combinations are available to facilitate simultaneous visualization of the different colours, and wedge-free filters allow sequential photography of images in each colour without image shift.

Enzymatically Induced Fluorescence

In general, enzyme activity is demonstrated by fluorescence microscopy as follows. A substrate is offered to the enzyme, which is allowed to act on the substrate to obtain a reaction product which is localized at the site of enzyme activity and is either fluorescent or easily rendered so. The technique is usually used for qualitative purposes only, to demonstrate the location of enzyme

activity, but quantification of enzymatic activity and estimation of Michaelis–Menten constants (K_m) are possible. It is usually easier to demonstrate the presence of the enzyme protein using immunofluorescence, but of course this does not guarantee that the enzyme system is active.

Applications

Fluorescence microscopy is widely used in biology and medicine, as well as in other fields. The literature is vast, and only a very brief outline of actual or potential applications can be presented here.

Fluorescence techniques can be applied to all kinds of material. Because fluorescence microscopy requires more complex and expensive instrumentation than conventional transmitted-light microscopy, fluorescence microscopy is usually reserved for those applications in which its high sensitivity is of importance: i.e. to examine substances present in low concentrations. Fluorescence microscopy can also be applied to detect particles below the resolution of a light microscope, and in histochemistry to visualize substances which cannot be seen by conventional microscopy – e.g. neurotransmitter amines. Biological material is commonly stained in some manner with a fluorescent stain.

Biological Applications

Probably the most important applications of fluorescence microscopy are to the study of living cells and tissues, to protein tracing by the Coons fluorescent antibody technique and to the study of nucleic acids by *in situ* hybridization.

Fluorescence microscopy has long been used in the study of living tissues (Table 3). This is possible because fluorescence microscopy reveals the position of very tiny

amounts of fluorescent substances, which can be introduced into living tissues or cells. Information about the environment of fluorescent probes in the tissues can be obtained by measuring changes in the fluorescence spectrum or other characteristics. This technique is now widely applied to the *in vivo* study of the concentration of various inorganic ions. The measurements of pH and of calcium ion concentration are particularly important.

The viability of cells is testable by using fluorescent esters, such as 6-carboxyfluorescein diacetate, which are non-fluorescent and which (being non-polar) can pass through the cell membrane. Inside the cell, the ester is hydrolysed to release the free fluorescent anion (6-carboxyfluorescein), which, if the membrane is intact, accumulates inside the cell. Fluorescence is also widely used to demonstrate the ramifications of nerve cells, by injection or takeup of fluorochromes into or by living cells.

The discovery and use of green fluorescent protein (GFP) have dramatically enhanced and expanded the use of fluorescence microscopy in cell biology and other biological areas. Notably, GFP is typically less harmful to live cells than fluorescent probes that are often phototoxic, opening up the study of living cells and their processes. The gene for production of GFP can be spliced into the genome of an organism, such that when specific proteins are expressed, so too is GFP – allowing the fluorescent detection of specific expression. Likewise, GFP can be used for specific tagging and tracking of proteins in living organisms. Analysis of the time course of such fluorescence has led to a far greater understanding of many biological processes in living systems including protein folding, protein transport and RNA dynamics. The utility of GFP has also led to automated systems for detection and analysis of cells.

Mineralogical Applications

Fluorescence microscopy is widely and routinely used for the study of coal.

Technological Applications

Fluorescence microscopy is ideal for studies of porosity in ceramics, using a fluorescent dye. It is also applicable to studies of semiconductors.

Table 3 Some examples of fluorescent probes used in living tissues

Application	Probes
Bone growth	Tetracycline, chlortetracycline
Calcium ions	Fura-2, Indo-1, Calcium Green
Magnesium ions	Mag-Fura-2
Membrane lipids	ANS, SITS, Nile Red
Mitochondria	Rhodamine 123, DASPI, DASPMI
Neoplasia	Haematoporphyrin derivative
Neuronal tracing	Fast Blue, Lucifer Yellow
Nuclei	Acridine Orange, bisbenzimidazole, ethidium bromide
pH Indication	BCECF, carboxyfluorescein, dicarbocyanines
Streaming (plant cells)	Ethidium bromide
Viability	6-Carboxyfluorescein diacetate

Symbols

H_H	intensity of horizontal emission from horizontal excitation
H_V	intensity of horizontal emission from vertical excitation
I_T	total emission intensity
M	molar mass
$p(\lambda)$	fluorescence polarization at wavelength λ
$r(\lambda)$	fluorescence anisotropy (at wavelength λ)
r_0	intrinsic anisotropy
t	time
V_H	intensity of vertical emission from horizontal excitation
V_V	intensity of vertical emission from vertical excitation
η	viscosity
$\kappa(\lambda)$	V_H/H_H correction factor
τ	fluorescence lifetime
ϕ	rotational correlation time

Fluorescence polarization techniques have proved to be a very useful method of investigating the environment and motion of fluorescent molecules and fluorophores within larger macromolecules.

When molecules are illuminated by plane-polarized light, those with their transition electric dipole moment parallel with the plane of polarization will preferentially absorb the light ('photoselection'). Subsequent emission of light from this excited electronic state, as the molecule returns to the original electronic ground state, will be similarly polarized parallel to the transition moment of each molecule. If the molecules are unable to rotate during the lifetime of the excited state, then the plane of polarization of the emitted light will be consistent and directly related to that of the exciting light (their electric vectors will be parallel). However, if the molecules are able to rotate within this time period, then the degree of polarization will be diminished. A similar description can be envisaged for fluorophoric groups within larger molecules; in this case, the rotational relaxation involves the tumbling of the complete molecule together with the localized motion of the fluorophore with respect to the molecular environment.

Although rotational relaxation is the main mechanism for loss of polarization, other phenomena can also contribute to depolarization, not least radiationless transfer among fluorophores. Furthermore, if the emission occurs

between a different pair of electronic states from that of the original absorption, with differently oriented transition moments with respect to the molecular axes, then a change in polarization may be observed.

Steady-State Anisotropy

In a typical fluorescence spectrometer, the excitation beam illuminating the sample and the optical path employed to detect the emission are orthogonal to each other and define a 'horizontal' plane. By employing linear polarizers before and after the sample, the plane of polarization of the excitation beam can be controlled and the polarization components of the emitted light determined. Specifically, by orientating the polarizers as either parallel or perpendicular to the horizontal plane, the plane of polarization of the excitation or detected emission can be described as either parallel to the plane (H, for horizontal) or perpendicular to it (V, for vertical). Four emission spectra can then be acquired:

V_V = intensity of vertical emission from vertical excitation

H_V = intensity of horizontal emission from vertical excitation

V_H = intensity of vertical emission from horizontal excitation

H_H = intensity of horizontal emission from horizontal excitation.

In these circumstances, for an *ideal* instrument, the *fluorescence polarization*, $p(\lambda)$, for a sample at a given wavelength λ is

$$p(\lambda) = \frac{(V_V - H_V)}{(V_V + H_V)} \quad [1]$$

and the corresponding *fluorescence anisotropy*, $r(\lambda)$, as

$$r(\lambda) = \frac{(V_V - H_V)}{(V_V + 2H_V)} \quad [2]$$

In principle, this would allow the fluorescence polarization or anisotropy to be determined with just two spectral acquisitions: V_V and H_V . However, in practice, it is vital to correct for the differing efficiencies of the emission monochromator and detector toward vertically and horizontally polarized light, which may be substantial. Consequently, for isotropic samples, eqn [1] can

be amended to

$$p(\lambda) = \frac{(V_V - \kappa(\lambda)H_V)}{(V_V + \kappa(\lambda)H_V)} \quad [3]$$

where

$$\kappa(\lambda) = V_H/H_H \quad [4]$$

and similarly for the fluorescence anisotropy,

$$r(\lambda) = \frac{(V_V - \kappa(\lambda)H_V)}{(V_V + 2\kappa(\lambda)H_V)} \quad [5]$$

The basis for the correction ratio κ is that, for horizontally polarized excitation of isotropic samples, the resulting vertically and horizontally polarized fluorescences detected should be of equal intensity; any difference may be attributed to the polarization dependence of the emission monochromator and detector.

The fluorescence polarization (p) and anisotropy (r) formalisms essentially embody the same information and each has its virtues and applications. In the realms of chemical and biochemical phenomena, where multiple fluorophores may be present, anisotropy has the advantage in possessing a linear relationship with mixture composition; the mean anisotropy of a mixture of species with fractional intensities f_i and individual anisotropies r_i is given by simply the sum of their products.

$$\bar{r} = \sum_i^{\text{Fluo.}} f_i r_i \quad [6]$$

Nonetheless, the polarization and anisotropy can be readily interconverted where necessary via

$$p = \frac{3r}{2+r} \quad [7]$$

$$r = \frac{2p}{3-p} \quad [8]$$

The fluorescence polarization $p(\lambda)$ and anisotropy $r(\lambda)$ both take the value of unity where there is a complete preservation of polarization during the excited-state lifetime (e.g., if the molecules are immobile and aligned for maximal absorption). Likewise, they both take the value of zero if there is a complete loss of polarization (i.e., a fast randomization of orientation). However, their values differ for cases between these extremes. In principle $-1 < p < 1$ and $-0.5 < r < 1$, although the limits are rarely encountered; negative values may be indicative of processes beyond depolarization through rotational relaxation, such as transitions to other excited states. In the case of an isotropic, randomly orientated distribution of molecules, the consequences of photoselection dictate

that the maximal anisotropy is $r = 0.4$ (corresponding to $p = 0.5$).

If the only significant process for depolarization is rotational relaxation, then the fluorescence anisotropy, for a single molecule or fluorophore, may be given by a form of the Perrin equation:

$$r = \frac{r_0}{(1 + \tau/\phi)} \quad [9]$$

where τ is the fluorescence lifetime, ϕ is the rotational correlation or relaxation time for the fluorophore's tumbling, and r_0 is the intrinsic anisotropy in the absence of rotational relaxation. Small molecules (less than 1000 Da molecular mass) with fluorescence lifetimes of the order of $\tau = 10$ ns are able to tumble with relative ease in low-viscosity solvents (e.g., water), typically $\phi = 0.1$ ns and thus $\tau \gg \phi$, and there is almost complete depolarization during the fluorescence lifetime ($r \rightarrow 0$). In contrast, a fixed fluorophore in a large protein may have the same fluorescence lifetime, but a rotational relaxation time of $\phi = 10$ ns, so that $\tau \sim \phi$ and there is significant preservation of the polarization.

As a convenient rule of thumb, the rotational relaxation time (in nanoseconds) for a spherical molecule of mass M (g mol^{-1}) in a medium of viscosity η ($\text{g cm}^{-1} \text{s}^{-1}$) is

$$\phi \approx 0.03 \eta M \text{ ns} \quad [10]$$

with, for example, $\eta = 0.01 \text{ g cm}^{-1} \text{s}^{-1}$ for water.

In the case of a small fluorescent molecule binding to a large macromolecule, the bound form should be distinguishable from the unbound form by having a substantially greater fluorescence anisotropy. Likewise, fluorophores rigidly held within a macromolecule would show significantly greater anisotropies than those exposed to the solvent and possessing some degree of motional freedom. Thus, one can employ fluorescence anisotropy to locate groups within a structure. This can prove particularly powerful if an environmental change (including perhaps the binding of a compound) induces a change in rigidity about observable fluorophores. Finally, if the variation in fluorescence anisotropy is plotted against wavelength, spectroscopic bands originating from distinct transitions or fluorophores may be distinguished by their differing anisotropies.

Fluorescence Lifetime Anisotropy

By the use of fluorescence lifetime instrumentation, one can further determine the evolution of the fluorescence anisotropy with time during and beyond the lifetime of the excited state. In the simplest case of a fluorophore in solution, with a single fluorescence lifetime and

depolarization through rotational relaxation alone, the fluorescence anisotropy will decay according to

$$r(t) = r_0 \exp(-t/\phi) \quad [11]$$

whereas the total emission intensity, $I_T(t)$, will decay as

$$I_T(t) = I_T(t_0) \exp(-t/\tau) \quad [12]$$

Thus, the rotational relaxation and fluorescence lifetime may be directly distinguished.

In more complex cases, perhaps involving binding kinetics or multiple environments, it is possible to deduce characteristic half-lives for the various processes. For example, one may identify subpopulations of molecules that are bound in different modes and even characterize the residual motion of a molecule while it is bound to a site that is itself tumbling. Nonetheless, these complex applications all require a sufficiently

robust hypothesis regarding the phenomena being modeled if the interpretations are to be valid.

Abbreviations

FRET	fluorescence resonance energy transfer
RET	resonance energy transfer

Fluorescence spectroscopy is a powerful method that can be applied to diverse biological problems. It relies on the intrinsic chromophores that many native protein sequences contain, for example, tryptophan side chains. Alternatively, nonnative chromophores can be site-specific introduced into both protein and DNA molecules. Fluorescence is a form of luminescence, which is defined as the emission of light from any substance. For electronically excited states, there are two types of luminescence: fluorescence and phosphorescence. This article will mainly discuss some basic fluorescence methods.

Phosphorescence

Phosphorescence is emission of light from triplet-excited states, in which the electron in the excited orbital has the same spin orientation as the ground-state electron. Transitions to the ground state are spin-forbidden, and the emission rates are relatively slow (10^3 to 100 s^{-1}). Therefore, phosphorescence lifetimes are typically milliseconds to seconds. Phosphorescence is usually not seen in fluid

solutions at room temperature because there are many deactivation processes that have faster rate constants, such as nonradiative decay and quenching processes. These processes effectively compete with photon emission in liquid solutions, thus reducing phosphorescence.

Fluorescence

Fluorescence is defined as emission of photons from singlet-excited states, in which the electron in the excited orbital is paired (of opposite sign) to the second electron in the ground-state orbital. Return to the ground state is spin-allowed and occurs rapidly by emission of a photon. The emission rates of fluorescence are typically 10^8 s^{-1} , so that a typical fluorescence lifetime is near 10 ns. Basic fluorescence spectral data are generally presented as emission spectra. The intensities and wavelengths of these spectra can vary widely depending on the chemical structure of the fluorophore and the solvent in which it is dissolved.

Jablonski Diagram

Processes that occur between the absorption and emission of light are usually illustrated by a Jablonski diagram. Two typical Jablonski diagrams of differing complexities are shown in **Figures 1** and **2**. The ground and first electronic

Figure 1 A simplified Jablonski diagram with absorbance, internal conversion, fluorescence, intersystem crossing, and phosphorescence.

Figure 2 A more complex Jablonski diagram with fluorescence, collisional quenching, and resonance energy transfer (RET). The symbol k_{nr} is used to represent all nonradiative paths to the ground state besides quenching and RET.

states are depicted as S_0 , and S_1 , respectively. At each of these electronic energy levels, the fluorophores can exist in a number of vibrational energy levels (denoted by 0, 1, 2, etc.). Transitions between states are depicted as vertical lines to illustrate the instantaneous nature of light absorption. Transitions occur in approximately 10^{-15} s, a time too short for significant displacement of nuclei (Franck–Condon principle).

Following light absorption, several processes that usually occur are as follows:

- **Fluorescence** A fluorophore is usually excited to some higher vibrational level of the excited electronic state. Molecules in condensed phases rapidly relax to the lowest vibrational level of S_1 . This process, called internal conversion, is nonradiative (does not emit a photon) and takes place in 10^{-12} s or less. Return to the ground electronic state also occurs to an excited vibrational level, which also quickly decays to reach thermal equilibrium. An interesting consequence of emission to an excited vibrational ground state is that the emission spectrum is typically a mirror image of the absorption spectrum of the $S_0 \rightarrow S_1$ transition.
- **Intersystem Crossing** Molecules in the S_1 state can undergo a spin conversion to the first excited triplet state, T_1 when the vibrational energies of the two excited states overlap. As discussed earlier, emission from T_1 is termed phosphorescence; these photons are generally shifted to longer wavelengths (lower energy) relative to fluorescence.

$h\nu_F < h\nu_A$. The phenomenon is known as the Stokes shift and can be caused by:

- a. Energy losses due to relaxation to ground vibrational states
- b. Solvent effects
- c. Excited-state reactions
- d. Complex formation
- e. Energy transfer

Solvent Reorientation

Rotational motions of small solvent molecules (like water) in fluid solution are rapid, typically occurring on a timescale of 40 ps or less. The relatively long timescale of fluorescence (nanoseconds) allows ample time for the solvent molecules to reorient around the excited-state dipole. This has the effect of lowering the energy of the excited state; consequently the energy of the fluorescent photon is also lower, which shifts the emission to longer wavelengths. This process is called solvent relaxation and occurs in 10^{-10} s in fluids. The high sensitivity of emission spectra to solvent polarity originates from this process, and can result in a substantial Stokes shift. In proteins, this is most recognized with the tryptophan residues that absorb light in the range of 280–295 nm. The typical fluorescence emission of free tryptophan in solution occurs near 350 nm, but this can be shifted to lower or higher wavelengths depending on whether the tryptophan environment is apolar or polar, respectively.

Characteristics of Fluorescence Emission

Stokes Shift

The energy of emission is typically less than that of absorption. Thus, fluorescence occurs at longer wavelengths,

Lifetime and Quantum Yield

The fluorescence lifetime and quantum yield are important characteristics of a fluorophore. The quantum yield is defined as the number of emitted photons relative

to the number of absorbed photons:

$$Q = \frac{\Gamma}{\Gamma + k_{nr}} \quad [1]$$

where Γ is the number of photons emitted and k_{nr} is all forms of nonradiative decay from the excited to the ground state. Nonradiative decay is any decay that does not involve the emission of a photon; one example is the dissipation of excited-state energy to vibrational and rotational modes of water. The quantum yield can be close to unity if the nonradiative decay rate is much smaller than the radiative decay rate, $k_{nr} \ll \Gamma$.

The lifetime of the excited state, τ , is defined by the average time the molecule spends in the excited state before returning to the ground state. Generally, fluorescence lifetimes are on the order of nanoseconds. The lifetime can be measured by an experiment diagrammed in **Figure 3** in which a very short, pulsed excitation is given followed by measurement of the time-dependent intensity. For a single exponential decay one can write

$$I(t) = I_0 \exp(-t/\tau) \quad [2]$$

where $I(t)$ and I_0 equal the intensities at time t and immediately after the pulse, and τ is the experimental lifetime. Thus, the lifetime is calculated from the slope of a plot of $\log I(t)$ versus t . Note that the observed lifetime is the inverse of the total decay rate, $(\Gamma + k_{nr})^{-1}$. The lifetime of the fluorophore in the absence of nonradiative processes is called the intrinsic lifetime and is given by $\tau_n = 1/\Gamma$.

It is important to keep in mind that fluorescence emission is a random process, and few molecules emit their photons precisely at $t = \tau$. This time is just the

Figure 3 Collection of time-domain lifetime measurements. These are collected by an excitation pulse followed by monitoring the emission intensity as a function of time.

average lifetime of a fluorophore's excited state. Although not discussed in any detail here, time-domain measurements are an area of active research and can be used to distinguish fluorophores on the same molecule. Consider a protein with two tryptophan residues. Because of the spectral overlap of absorbance and emission, it is not usually possible in a steady-state experiment to resolve the emission spectra from the two residues. How is each of the tryptophan residues affected by interactions with the rest of the protein? Is one close to the binding site and the other far away? Are both affected or is only one affected? These questions can be addressed using a time-domain experiment.

Fluorescence Quenching

Fluorescence quenching refers to any process that decreases the fluorescence intensity of a sample. There is a wide variety of quenching processes that include excited-state reactions, molecular rearrangements, ground-state complex formation, and energy transfer. Quenching experiments can be used to determine the accessibility of quencher to a fluorophore, to monitor conformational changes, and to monitor association reactions when the fluorescence of one of the reactants changes upon binding.

There are two basic types of quenching: static and dynamic (collisional). Both types require an interaction between the fluorophore and the quencher. In the case of dynamic quenching, the quencher must diffuse to the fluorophore during the lifetime of the excited state. On contact, the fluorophore returns to the ground state without emission of a photon. In the case of static quenching, a complex forms between the ground-state fluorophore and the quencher, and this complex is non-fluorescent. The formation of this static quenching complex does not rely on population of the excited state. They will be considered independently.

Collisional Quenching

Collisional quenching occurs when the excited-state fluorophore is deactivated by contact with some other molecule in solution, which is called the quencher. The molecules are not chemically altered in the process. For collisional quenching, the decrease in intensity is described by the ratio of the fluorescence in the absence of quenching to the presence of quencher by the Stern–Volmer equation:

$$\frac{F_0}{F} = 1 + K[Q] = 1 + k_q\tau_0[Q] \quad [3]$$

where F_0 and F are the observed fluorescence in the absence and presence of quencher, K is the Stern–Volmer

quenching constant, k_q is the bimolecular quenching constant, τ_0 is the lifetime in the absence of quencher, and $[Q]$ is the quencher concentration. The Stern–Volmer constant is sometimes abbreviated as K_{SV} or even as K_D . The use of the K_D abbreviation seems very unwise, since it could lead to confusion. Thus, the reader should be aware of the context in which this term is being used.

Mechanisms of Quenching

The accessibility of fluorophores to quenchers can be used to determine the location of fluorescent probes on macromolecules, and a wide variety of molecules can act as collisional quenchers. The mechanism varies with the fluorophore–quencher pair, but they must all be able to interact with the fluorophore, which gives some information about its accessibility. Common substances used for collisional quenching are halides: bromide and iodide (I^-), oxygen, and acrylamide.

Mechanisms of quenching are subject to debate. In the case of oxygen, which is paramagnetic, it is thought that it may cause the fluorophore to undergo intersystem crossing to the triplet state. In fluid solutions, these long-lived triplet states decay by nonradiative means before phosphorescence can occur. Halides such as iodine and bromine are also thought to cause intersystem crossing to the excited triplet state, promoted by spin–orbit coupling of the excited-state fluorophore and the halogen. Other quenchers, such as Cu^{2+} , Pb^{2+} , Cd^{2+} , and Mn^{2+} , are thought to cause the donation of an electron from the fluorophore in the excited state.

Stern–Volmer Plot

Because of the linear dependence, quenching data are usually presented as plots of F_0/F versus $[Q]$. These plots should yield an intercept of unity on the y-axis and a slope equal to K_{SV} . It is useful to note that $1/K_{SV}$ is the quencher concentration at which $F_0/F = 2$, or 50% of the intensity is quenched. A linear Stern–Volmer plot is generally indicative of a single class of fluorophores that are all equally accessible to the quencher. If two fluorophore populations are present, and one class is not accessible to the quencher, then the Stern–Volmer plots deviate from linearity toward the x-axis (downward). This result is frequently found for the quenching of tryptophan fluorescence in proteins by polar or charged quenchers.

Static Quenching

Static quenching involves the formation of a complex between the quencher and the fluorophore that does not rely on diffusion in the excited state. The dependence of the fluorescence intensity on quencher concentration for

static quenching is derived from consideration of the association constant for complex formation:

$$K_S = \frac{[FQ]}{[F][Q]} \quad [4]$$

where K_S is the fluorophore–quencher association constant, $[FQ]$ is the concentration of the complex, $[F]$ is the concentration of the uncomplexed fluorophore, and $[Q]$ is the concentration of quencher. Since the total concentration of the fluorophore, $[F]_T$, is given by $[F]_T = [F] + [FQ]$, the static quenching constant can be written as follows:

$$K_S = \frac{[F]_T - [F]}{[F][Q]} = \frac{[F]_T}{[F][Q]} - \frac{1}{[Q]} \quad [5]$$

which rearranges to

$$\frac{[F]_T}{[F]} = 1 + K_S[Q] \quad [6]$$

By recognizing the fluorescence signal in the absence of quencher, F_0 would correspond to the total concentration of fluorophore; one can substitute the fluorescence intensities F_0 and F for the total and free concentrations $[F]_T$ and $[F]$, respectively, to obtain

$$\frac{F_0}{F} = 1 + K_S[Q] \quad [7]$$

which will be recognized is exactly the same linear equation that is used for dynamic quenching.

Both Static and Dynamic Quenching Can Have a Linear Stern–Volmer Plot

Since both static and dynamic quenching result in a linear Stern–Volmer plot, they cannot be distinguished by a single experiment; however, they are distinguished from each other by their differing dependences on temperature, viscosity, and/or lifetime measurements. For example, an increase in temperature leads to an increase in the diffusion constant of the quencher and will generally lead to an increase in collisional quenching. In contrast, an increase in temperature will usually lead to a decrease in the binding constant of the quencher for fluorophore and will result in a decrease in quenching for a static quencher.

Resonance Energy Transfer

Resonance energy transfer (RET) is the transfer of the excited-state energy from an initially excited fluorophore, called the donor, to a second molecule, called an acceptor. This reduces the fluorescence of the donor and can be considered as a quenching process. The transfer of

Figure 4 Resonance energy transfer occurs when the acceptor absorption energies overlap with the donor emission energies.

energy from the donor to the acceptor occurs when the emission spectrum of a donor overlaps with the absorption spectrum of the acceptor as shown in **Figure 4**. Importantly, the acceptor does not need to be fluorescent for energy transfer. A property of RET is that it is nonradiative: it does not involve emission of a photon by the donor in the classical sense. Rather, the energy transfer occurs when the donor and acceptor chromophores are electronically coupled by a long-range dipole–dipole interaction. For these reasons, the term RET is preferred to the term fluorescence resonance energy transfer (FRET), which is also commonly used.

The extent of RET is determined by the distance between the donor and the acceptor (**Figures 5 and 6**) as well as the extent of spectral overlap (**Figure 4**). For convenience, the spectral overlap is described in terms of the Förster distance, R_0 , which is defined as the distance at which the RET is 50% efficient (**Figure 6**). The rate of energy transfer between the donor–acceptor pair, $k_T(r)$, is given by

$$k_T(r) = \frac{1}{\tau_D} \left(\frac{R_0}{r} \right)^6 \quad [8]$$

where r is the distance between the donor and the acceptor and τ_D is the lifetime of the donor in the absence of energy transfer. **Figure 6** shows that the transfer rates are very fast at short distances. At the Förster distance, the donor emission would be decreased to one-half of its intensity in the absence of acceptor because the rate of transfer equals the decay rate of the donor in the absence of the acceptor. At a fixed distance, the efficiency of energy transfer for a single donor–acceptor pair at a fixed distance equals:

$$E = \frac{R_0^6}{R_0^6 + r^6} \quad [9]$$

Figure 5 Energy transfer rate depends inversely on the separation distance, r , between the donor and the acceptor.

Förster distances are comparable in size to biological macromolecules, 20–90 Å, and energy transfer is, therefore, convenient for studies of biological macromolecules. Anything that affects the donor–acceptor distance will affect the rate of energy transfer. As a consequence, energy transfer has been used as a ‘spectroscopic ruler’ for measurements of distance between sites on macromolecules and the effects of conformational changes on these distances. Binding reactions can also be measured using RET, since it is only possible when two reactants are close together.

Fluorescence Anisotropy

Anisotropy measurements provide information on the size and shape of proteins or the rigidity of various molecular environments. These are based on the principle of photo-selective excitation of fluorophores by polarized light. In an isotropic solution, the fluorophores are oriented randomly. Excitation with polarized light will result in a selective excitation of those fluorophore molecules whose absorption transition dipole is parallel to the electric vector of the excitation as shown in **Figure 7**. This selective excitation results in a partially oriented population of polarized fluorescence emission. Emission also occurs with the light polarized along a fixed axis in the fluorophore. The relative angle between these moments determines the maximum measured anisotropy in the absence of other molecular rearrangements. The fluorescence anisotropy, R , and

Figure 6 The dependence of energy transfer on the distance between the donor and the acceptor fluorophores. The top panel shows the efficiency of transfer, which is 50% at the Förster distance. The bottom panel shows the rate of transfer, which is equal to the intrinsic donor decay rate at the Förster distance.

polarization, P are defined by:

$$R = \frac{I_{\parallel} - I_{\text{Per}}}{I_{\parallel} + 2I_{\text{Per}}} \quad [10]$$

and

$$P = \frac{I_{\parallel} - I_{\text{Per}}}{I_{\parallel} + I_{\text{Per}}} \quad [11]$$

where $I_{\parallel}$ and I_{Per} are the fluorescence intensities of the vertically and horizontally polarized emission when the sample is excited with vertically polarized light. The anisotropy is a dimensionless quantity that is independent of the total intensity of the sample.

Several phenomena can decrease the measured anisotropy to values lower than the maximum theoretical values. The most common cause is rotational diffusion of a macromolecule to which the fluorophore is attached. Such rotation diffusion occurs during the lifetime of the excited state and displaces the emission dipole of the fluorophore. Conveniently, rotation correlation times for macromolecules are on the order of nanoseconds. For example, the rotational correlation time for human serum albumin is approximately 50 ns. Anisotropy is especially useful for measuring binding; when a macromolecule binds a ligand, the complex will be bigger and will have a longer rotational correlation time. This can be observed as a change in the anisotropy of the complex with respect to the unliganded macromolecule.

In addition to binding, there can be segmental motion of the fluorophore about its bonds, which happens on the picoseconds timescale. In this case, the fluorescent molecules can rotate many times during the 1–10-ns excited-state lifetime, and the orientation of the polarized emission can be randomized. When this occurs, there is a

Figure 7 Principle of the fluorescence anisotropy experiment.

diminished ability to observe any changes in the rotational correlation time of the molecule to which the fluorophore is attached, but this can be countered if the fluorophore becomes immobilized when the macro-molecule binds a ligand.

When bound to a macromolecule and assuming no other processes result in loss of anisotropy, the expected anisotropy is given by the Perrin equation:

$$r = \frac{r_0}{1 + (\tau/\theta)} \quad [12]$$

where r_0 is the anisotropy that would be measured in the absence of rotational diffusion and θ is the rotational correlation time for the diffusion process. For a sphere

$$\theta = \frac{\eta V}{RT} \quad [13]$$

where η is the viscosity and V is the molecular volume equal to $M(\bar{v} + b)$, where M is the molecular weight, $\bar{v}$ is

the partial specific volume, and b is the hydration of the molecule. In this case, the binding of the probe has slowed the probes' rate of rotational motion.

Introduction

Fluorescent methods have been extensively developed for analytical purposes. Owing to their specificity and sensitivity, fluorescent molecular probes (FMP) are presently largely used for the labelling of living cells. Numerous applications in biomedical research, including pharmacology and toxicology, are in progress. Initially, only flow cytometry was capable of quantifying fluorescent signals in cell biology and obtaining information such as cell type characterization, antigen expression, cell receptor localization and so on. More recently, the most important advances have resulted from the combination of probe development for exploring specific cellular functions *in situ* and the use of performing instrumentation. Spectrofluorimetry associates the high sensitivity of fluorescence with the reproducibility of microplate reading. Moreover, new probes continue to be developed and automatic procedures are available for monitoring analysis and producing a variety of tests used in cell biology, microbiology, toxicology and oncology. Several reviews and monographs on molecular fluorescent probes are available in the bibliography and are listed in the section 'Further Reading'.

Micromethods are one of the most recent applications of fluorescence, and efforts are devoted to the adaptation of apparatus capable of direct measurement on cell culture microplates that can be automatically scanned. In basic research, as well as in pharmaceutical drug development, this advanced technology represents a significant gain in productivity and cost control. This article deals first with probe labelling strategy, choice of suitable devices for microplate reading and data analysis. Secondly, selected applications are discussed.

Fluorescent Molecular Probes and Practical Considerations

Fluorescence theory and applications have been documented by Guilbault. According to this author, a fluorescent probe could be defined as a chromophore that undergoes changes in absorption characteristics as a function of environmental disturbance. The molecule absorbs energy, rises to an excited state, and then returns to its normal state, concomitantly emitting energy as

photons. This light emission is named fluorescence. The optimum difference between excitation and emission wavelengths (the Stokes shift) lies between 20 and 50 nm.

Several cellular functions are revealed by probes which react stoichiometrically and thus lead to a quantitative relationship between probe and target. In fact, fluorescent probes are versatile tools that can be used to reveal specific cell properties, such as information about cell structure, function, viability, proliferation or differentiation. Probes include fluorescent dyes, antibodies coupled with fluorochromes or fluorogenic substrates, and oligonucleotides. New fluorescent probes are being constantly developed, and additional fluorescent indicators can be found in catalogues or Web pages of a few specialized companies; among them are Molecular Probes (Invitrogen) and Fluka Biochemicals (Sigma Aldrich). A probe is generally selected because of its specific spectroscopic properties: fluorescence lifetime, fluorescence intensity, or functional characteristics—cellular incorporation and behaviour under pH variation. To minimize cellular probe disturbance, that is possible chemical interactions between probe and the tested xenobiotic, low probe concentrations (micro- to nanomolar) must be used. Moreover, to avoid photochemically induced reactive oxygen species production, all experiments have to be carried out with as little light present as possible. It is also necessary to consider quenching, which results in fluorescence reduction by absorption of emitted light by a fluorophore or other substances present in the medium, such as phenol red.

Currently, there is a wide variety of highly fluorescent extrinsic dyes that may be grouped in two classes:

- fluorescent exclusion probes, which do not penetrate into the cell and so maintain its integrity;
- vital fluorescent probes, which are incorporated into living cells. The latter are more frequently used and can be divided into four subclasses:
 - probes related to membrane integrity;
 - probes related to membrane potential;
 - probes related to DNA content;
 - probes related to ion content.

Fluorescent probes and their derivatives commonly used in microspectrofluorimetry are listed in **Table 1** with their specific spectra in UV, visible and near IR areas.

The structures of some of the probes mentioned later are given in **Figure 1**.

Concerning Cells

Adherent or nonadherent cells could be obtained from either primary cultures or immortalized cell lines. Although better reproducibility is generally obtained with cell lines, with careful monitoring very good results have also been obtained with primary cell cultures. Concerning adherent cells, for better reproducibility, the cell monolayer should be used only when subconfluent. In such controlled condition, the cell outline is clearly visible (**Figure 2a**). Nonadherent cells in suspension must be carefully isolated before distribution into each well (**Figure 2b**). In both cases, monolayer variability or cell clusters should be avoided. Moreover, cellular autofluorescence has to be precisely measured before experiment, although there is a generally low fluorescence background when the labelling procedure is well adapted. The morphology and integrity of the cells and their distribution at the bottom of the microplate have to be monitored to see if they are correctly reproduced from one set to another, paying particular attention to optimization of the culture support. The best optical design is represented by plates with a transparent flat bottom and black edges, but by accepting some cross-contamination between wells, standard culture supports can be used in most apparatus. An optimal distribution of microplated cells is shown in **Figure 3**. The cell population could vary in terms of staining levels due, in part, to the state of the type of cells. In any case, the methodology has to be adapted to each cell type and

controlled by fluorescence microscopy. Besides validating a new procedure, a comparison could also be made by using fluorescence-activated cell sorting (FACS).

Choosing a Fluorescent Probe

The choice of a probe depends on the function or the major target to be explored. The first step of the labelling procedure is the determination of the concentration–response relationship between the probe and the fluorescent signal. Toxic effects of probes related to their concentration are easily controlled, as is nonrelease of the probe, when experiments are carried out in dilute samples. Higher concentration could induce leakage or quenching. The probe stability in the storage solvent and the culture medium has to be controlled. As deleterious effects and structural damage have been observed in loaded cells exposed to high light energy, potential phototoxic effects, that is peroxidative damages or necrosis, must be considered. Moreover, probes may be photolabile, and thus, it is necessary to expose the sample in the wells for a short time, at the lowest possible light energy. In these experimental conditions, phototoxic interferences are minimized. In most apparatus, the microplate is scanned at a defined wavelength for 0.3 s, which results in limited fading.

General Labelling Procedure

In all cases, whatever the probe used, concentration–response and kinetics curves should be established. These studies will indicate the optimal concentration and incubation time for the probe, depending on the cell type. As an example, calcein-AM (calcein acetoxymethylester) is used at 20 μM for lymphocytes and 5 μM for keratinocytes, at 37 °C, for a 30 min incubation period. Before loading, the cells are washed three times with PBS and then incubated with the appropriate concentration of the probe in PBS-BSA (0.2%) for 30 min. After elimination of the non-incorporated probe by centrifugation, labelled cells are distributed over the plate, in accordance with the scheme presented in **Figure 3**. The fluorescence is then rapidly monitored using a cytofluorimeter. All manipulations concerning the loading of cells with fluorophores are carried out, avoiding exposure to direct light. Generally, probes are aliquoted in a concentrated stock solution (0.1–1 mM) and diluted before use of the required final concentration. At low concentrations (below 50 μM), probes have little deleterious effect on cells. The efficiency of probe incorporation is temperature dependent, with an optimum at 37 °C. The excess probe is eliminated by gentle centrifugation, and the cell pellet is resuspended in the medium and examined under an inverted microscope. Finally, the fluorescence is measured using a microplate reader.

Selecting a Microplate Reader

The instrumentation for microspectrofluorimetry consists of two essential units: a source of radiation and a system for measuring the intensity of the fluorescence

emission. The basic components of this apparatus are shown in **Figure 4**. The different appliances available from various companies are compared in **Table 2**. As an energy source, the xenon lamp has a better continuum than that of the tungsten lamp in the ultraviolet spectrum. For this reason, the xenon lamp is the most widely used source of radiation in spectrofluorimetry.

For quantitative measurements, excitation and emission monochromators can be set at the optimum wavelength for the probe. Difficulties are encountered with apparatus according to the chosen plate-reading method above or below the plastic support of the microplate; to counter this, most manufacturers equip their instruments with two types of plate reader. To diminish interference with other biological molecules, longer wavelengths are preferred to shorter ones.

Environmental factors also have to be considered. The main inconvenience using fluorimetry comes from parameters such as (1) temperature: the decrease in fluorescence with temperature is estimated to be 1% per degree Celsius; consequently automated temperature control is of the upmost importance; (2) light bleaching: it is necessary to operate out of direct light; (3) pH. All appliances should serve as routine instruments and provide a wide range of excitation wavelengths. Most of them are provided with many accessories, such as automatic sample distributor, temperature regulator, shaking system and so on, as listed in **Table 2**. Sensitivity has increased such that $1 \text{ fmol}^{-1} \text{ well}^{-1}$ of fluorescein is now achievable.

Collecting Data (Interpretation)

Each test must be repeated at least three times, and each microplate has its own control with quadruple wells for each concentration. The intra-assay variability among quadruple concentrations must be less than 5%. The mean and standard deviation should be used in standard tests. Data could be exported into other programs and dealt with statistically. Plate-reader software, however, does possess graphical functions and data analysis capabilities. A wide range of graphical functions, such as linear regression and statistical tests, are included in most apparatus.

Microspectrofluorimetry: Biological Applications

In the following section, selected applications of fluorescence are briefly discussed, and experimental results given. Our aim will be restricted to the presentation of some specific probes which target different mechanisms of cytotoxicity, oxidative stress, detoxification potential or cellular adhesive capacities. We demonstrate here that the selection of the most appropriate method for early

detection of the cytotoxicity of xenobiotics is directly related to the mechanism of the toxic agent.

Fluorescent Probes for Studying Cell Viability

To study cell viability, several probes are proposed, as indicated in Table 3. Two examples will be given in this section. They correspond to either membrane damage (calcein-AM) or disturbance of mitochondrial potential (Alamar blue). Cell viability is often estimated by the Neutral red assay, which is widely used in classical

spectrometry and, more recently, in fluorimetry because of its increased sensitivity. More often than not, the fluorogenic dye calcein-AM can be used to provide a rapid and sensitive method for measuring cell viability as well as cell-cell and cell-substratum adhesion interactions. Calcein-AM is cleaved by intracellular esterases to produce highly fluorescent and well-retained calcein, independently of pH.

The mitochondrial membrane potential can be monitored using several fluorescent probes. These probes

are often cationic and accumulate in active mitochondria with a high membrane potential. A review of the use of rhodamine 123 has been published by Slavik. It is stated that the fluorescence intensity of rhodamine 123 in mitochondria of living cells could be quantified by various techniques such as fluorescence microscopy or FACS, and can also be used in microspectrofluorimetry. A new fluorimetric metabolic indicator for detecting mitochondrial activity (which reflects the viability of target cells) is Alamar blue. It is a redox indicator that gives fluorescence and visible colour changes in response to cellular metabolic activity. It acts as an intermediate electron acceptor in the electron transport system between the final reduction of O₂ and cytochrome oxidase. Alamar blue spectra are shown in **Figure 5**.

Performing calcein-AM assay in practice

To perform the assay, the probe is added at the concentration determined in preliminary experiments to each well before or after cell treatment with the xenobiotic, be it sodium dodecyl sulfate (SDS) (**Figure 6a**), dinitrophenol (DNP) (**Figure 6b**), or doxorubicin (**Figure 6c**). After incubation for 30 min, all wells are gently rinsed before scanning the microplate using an excitation wavelength of 490 nm and an emission wavelength of 530 nm. The calcein fluorescence in treated samples is compared to that of control cells, and the relative fluorescence intensity is used to calculate the viability percentage.

Performing Alamar blue assay in practice

After treatment with the studied xenobiotic, cells are carefully washed to eliminate proteins which decrease the rate of dye reduction. Alamar blue solution (10% final concentration in PBS) is added to each well, and after 2 h, supernatants are transferred to a separate 96-well culture plate and the fluorescence is monitored using an excitation wavelength of 560 nm and an emission wavelength of 590 nm.

The cytotoxicities of both DNP and SDS are presented in **Figure 6a** and **b**. For each compound, one can determine the cytotoxic concentration exerting 50% cell damage, that is 50% decrease in the fluorescent signal of control cells. Depending on the target, membrane or mitochondrial damage, the best test for SDS is the calcein-AM assay, whereas the Alamar blue assay is the most sensitive one for DNP.

Probes for Assessing Oxidative Stress

Intracellular peroxide levels were assessed using 2',7'-dihydrodichlorofluorescein diacetate (H2DCFDA), an oxidation-sensitive fluorescent probe. Once inside the cell, the probe is deacetylated by intracellular esterases forming 2',7'-dichlorofluorescein (H2DCF), which is oxidized in the presence of a variety of peroxides, to a highly fluorescent compound, namely 2',7'-dichlorofluorescein (DCF).

Performing H2DCFDA assay in practice

Cells are loaded with 10 µM H2DCFDA for microplate fluorescent analysis for 30 min. The fluorescence is quantified with the microtitreplate reader using an excitation wavelength of 480 nm and an emission wavelength of 538 nm, with three separate assays per treatment. This protocol was validated using well-known peroxide inducers, such as H₂O₂, cumene hydroperoxide and the t-butylhydroperoxide (t-BHP). For each compound, a concentration–response relationship is observed.

The sensitivity of the assay allows the early detection of the formation of reactive oxygen species (ROS) induced by doxorubicin, when applied to a monolayer of endothelial cells. Cells treated with 20 µg/ml of doxorubicin for 3 h revealed a 50% increase in ROS measured by the DCFDA assay (**Figure 6d**), which correlates with the cell viability estimated by the calcein-AM assay (**Figure 6c**).

Detoxification	Resorufin	Cytochrome P450 activity	Rat P et al. (1997) Microtitration fluorimetric assays on living cells: New tools for screening in cell pharmacotoxicology. In: van Zutphen LFM and Balls M (eds.), <i>Animal Alternatives, Welfare and Ethics</i> , pp. 813–825. Amsterdam: Elsevier.
Enzymatic systems	CMFDA Bromobimane	Glutathione transferases	Lilius H et al. (1996) A combination of fluorescent probes for evaluation of cytotoxicity and toxic mechanisms in isolated rainbow trout hepatocytes. <i>Toxicology in Vitro</i> 10: 341–348. Rat P et al. (1995) Cold light fluorimetry: A microtitration technology for cell culture to evaluate anethole dithiol-ethione and other thiols. <i>Methods in Enzymology</i> 252: 331–341.
Adhesion	Calcein-AM	Cytosolic enzymes	Braut-Boucher F et al. (1995) A non-isotopic, highly sensitive, fluorimetric, cell–cell adhesion assay using calcein AM-labeled lymphocytes. <i>Journal of Immunological Methods</i> 178: 41–51.

The study of the cytotoxicity of doxorubicin, a red-coloured molecule for which cytotoxic effects involve at least three mechanisms (necrosis/apoptosis, mitochondrial activity and oxidative stress) connected in some way or another, is a prime example to demonstrate the relevance of fluorimetric methods.

Probes for Assessing Intracellular Sulphydryl Levels

An easy and sensitive method to evaluate the function of the cellular detoxification mechanisms, which could possibly be linked to stress conditions, is valuable.

Glutathione (GSH), a tripeptide (Glu-Cys-Gly) which plays a key role in numerous metabolic processes, is a major intracellular reducing agent involved in detoxification of reactive species. A number of flow cytometric methods for measuring cellular GSH have been described using probes that form adducts with GSH. Cellular thiol levels could be analysed using either monobromobimane (mBBR), which forms a fluorescent adduct with sulphydryl groups, or 5-chloromethylfluorescein diacetate (CMFDA). CMFDA, a nonfluorescent molecule capable of permeating cells, becomes fluorescent after cleavage by cellular esterases. The GS

Figure 5 Fluorescence and absorbance spectra of Alamar blue (oxidized or reduced). Reprinted with permission from Interchim, France.

transferase catalyses the reaction between CMF and the intracellular thiols retained inside the cell, whereas the unconjugated probe is released in the medium and eliminated. A decrease in fluorescence reveals a decrease in GSH content.

Performing CMFDA assay in practice

To validate the CMFDA assay, intracellular sulphhydryl groups of the cells were depleted either by using *N*-ethylmaleimide (NEM), a thiol-depleting agent, or by inhibiting GSH synthesis with buthionine sulfoximine (BSO). An overnight incubation with 2 mM BSO reduces the fluorescent signal intensity by 30%, compared to control cultures, whereas a 2-min incubation with 100 μ M NEM induces a more acute depletion of 50%.

Cell–Cell Adhesion Assay

We have previously described a non-isotopic, highly sensitive, fluorimetric, cell–cell adhesion microplate assay using calcein-AM-labelled lymphocytes. To successfully perform the lymphocyte/keratinocyte adhesion assay, the following conditions are recommended:

- The confluence of the keratinocyte monolayer should be checked in each well;

- The lymphocytes should be labelled with 20 μ M calcein-AM and incubated for 30 min;
- A defined lymphocyte density per well should be plated onto the monolayer;
- Fluorescence should be monitored immediately using the fluorimetric microtitreplate reader to avoid probe release.

The percentage of lymphocytes adhering to the keratinocyte monolayer was calculated as follows:

$$\% \text{ adhesion} = \frac{F_A}{F_T - F_R} \times 100$$

where F_A is the fluorescence of adherent lymphocytes, F_T the fluorescence of total lymphocytes deposited, and F_R the released fluorescence. This equation takes into account the background fluorescence emitted by control wells in the spectrum considered.

This method can be easily applied to any cells whose adhesive capacities have to be investigated and can also be used to manage cell–extracellular matrix adhesion.

Concluding Remarks

The aim of this article was to introduce microspectrofluorimetry, using fluorescence probes, as a new technology in analytical fluorescent applications and provide practical guidelines to the use of this powerful technique. When compared with conventional methods, its main advantages are:

- high sensitivity and specificity;
- simultaneous monitoring of different cellular functions;
- combining two or more probes, if the probes emit at different wavelengths;
- use of coloured molecules without interference;
- easy handling, low cost and possibility of batch studies;
- increasing the number of available fluorescent probes and kits;
- avoiding the use of radiolabelled molecules.

Successful applications require the appropriate choice of model system and probes with the aim of defining the target cell functions. Under these conditions, microspectrofluorimetry offers innovative analytical tools for both research and development projects, as well as rapid and accurate assays for quality control. Cytofluorimetric microtitration has been recommended by the European Centre for Validation of Alternative Methods (see the section ‘Further Reading’). These methods, based on the selection of appropriate test systems, could give strong evidence for possible molecular mechanisms involved in cellular functions.

This article is reproduced from the previous edition, volume 1, pp 489–498, © 1999, Elsevier Ltd.

Fluorine-19 is spin 1/2, 100% abundant, and has a sensitivity relative to the proton of 0.83. It is a very easy nucleus to observe, and even prior to 1970 a great deal of information was obtained. ¹⁹F NMR has found wide-spread application in chemistry and biology: for example, the high-resolution ¹⁹F NMR study of polymers in solution furnishes relevant chemical information concerning polymer structures; furthermore, fluorine NMR can be useful for studying the binding of fluorinated molecules and macromolecules and membranes.

One reason for this wide application is that the wide range and the high sensitivity of the fluorine-19 chemical shift makes the resonance a very sensitive means of monitoring conformational, electronic and solvent effects and that it is possible to study fluorine bonded to nearly every element in the periodic table.

There is a sizeable literature on fluorine, and in particular several reviews with extensive compilations of ¹⁹F chemical shifts (solution state) and coupling constants, both in organic and in inorganic chemistry.

The nuclear properties of ¹⁹F are summarized in **Table 1**: the gyromagnetic ratio, 0.94 that of ¹H, indicates a basic resonance frequency of 188.1 MHz on a spectrometer which operates at a field strength of 4.7 T with ¹H NMR at 200 MHz.

Experimental Aspects

In ¹⁹F NMR experiments, a problem exists in the choice of chemical shift reference since the reactivity of some fluorine compounds has often precluded their use as internal standards. However, the standard reference compound most used is internal CFC1₃, a very volatile

and unreactive derivative, which unfortunately, like C₆F₆, has a sizeable temperature and solvent dependence: medium effects are, in fact, greater in ¹⁹F NMR spectroscopy than in that of ¹H NMR, the signal of several compounds being shifted by 2–10 ppm relative to the gas phase when the spectra are recorded in solvents such as *n*-heptane, CHCl₃ or CH₃I.

Unlike ¹H NMR, in ¹⁹F NMR experiments it is not very important to consider the bulk susceptibility contribution to the shielding, the relative error being negligible due to the larger shift for ¹⁹F than for ¹H with the same bulk susceptibility contribution. On the other hand, there are great difficulties in application of broad band decoupling owing to the large ²*J*(¹⁹F,¹H) coupling and the proximity of ¹H and ¹⁹F chemical shift resonance frequencies.

¹⁹F chemical information (for example, the magnitude and sign of ²*J*(¹⁹F,X) coupling constants) can be efficiently obtained from two-dimensional NMR methods such as ¹H–¹⁹F, ¹³C–¹⁹F and ¹⁹F–¹⁹F correlation spectroscopy (COSY). These methods are helpful in determining small long-range coupling constants and in spectral assignment in polyfluoro derivatives.

¹⁹F NMR chemical shifts cover such a wide frequency range that problems can occur with low digital resolution. For example, to cover a spectral width of approximately 400 ppm using a spectrometer which operates at 564 MHz for ¹⁹F (600 MHz for ¹H NMR) requires a data set comprising 512 k points to give a reasonable digital resolution. With modern computer systems this is not a problem. Alternatively, the use of digital filtering or selective pulse methods can negate the need for such large data sets.

Chemical Shift

Fluorine chemical shifts cover a very large range (more than 1300 ppm, about two orders greater than ¹H chemical shift) when organic, inorganic, and organo-metallic compounds are examined. **Table 2** exhibits selected ¹⁹F data all referenced to CFC1₃, a negative sign indicating a higher shielding or a shift to lower frequency. In several experiments, other compounds have been used as a chemical shift reference, so that to draw straightforward conclusions it is often necessary to convert the chemical shift values to the δ scale with CFC1₃ as reference, taking into account whether an external or internal standard has been used.

Table 1 NMR properties of fluorine-19

Property	Value
Spin	1/2
NA	100
<i>R</i> ^H	0.83
<i>R</i> ^C	4.73 × 10 ³
γ (10 ⁷ rad T ⁻¹ s ⁻¹)	25.1815
Ξ , MHz	94.094003

NA is the natural abundance (%); *R*^H and *R*^C are the receptivity relative to that of ¹H and ¹³C, respectively; γ is the gyromagnetic ratio; Ξ is the resonance frequency for the reference compound CFC1₃ in a magnetic field for which (Me)₄Si has a proton resonance of 100 MHz.

Table 2 Selected ¹⁹F chemical shifts in ppm relative to CFCl₃

Compound	δ(ppm)	Compound	δ(ppm)
HF	40	C ₆ H ₅ F	-116
F-C≡N	-156	C ₆ F ₆	-163
F-C≡C-F	-95	1,2-C ₆ F ₂	-139
F ₂ C=CF ₂	-135	1,3-C ₆ F ₂	-104

CFBr=CFBr(Z)	-95	IF ₇	170
CFCl=CFCl(E)	-120	CF ₃ COOH	-78
CFCl=CFCl(Z)	-105	1-Fluoronaphthalene	-123

Isotope Effects

Secondary isotope effects are relevant for ¹⁹F chemical shifts: the main known isotope effects have been observed with the standard CFCl₃ (**Figure 1**), its signal being split into four components of 21:21:7:1 intensity, corresponding to CF³⁵Cl₃, CF³⁵Cl₂³⁷Cl, CF³⁵Cl³⁷Cl₂ and CF³⁷Cl₃ compounds, due to the isotope effect of the ³⁵Cl and ³⁷Cl.

In F(H₂O)_x-HF-HF₂⁻ species, which generally are obtained when KF is dissolved in H₂O, the substitution of H with D produces a significant high-field ¹⁹F chemical shift. For this reason it is possible to use the ¹⁹F chemical shift changes of KF to determine the percentage of D₂O in H₂O/D₂O mixtures.

Solvent and Temperature Dependence of Fluorine Chemical Shifts

Fluorine chemical shifts are very sensitive to temperature and solvent even in the absence of chemical changes (e.g. electrostatic solute-solvent interactions such as hydrogen bond formation, dissociation and change in the structure of the compounds examined). Moreover, variable temperature ¹⁹F NMR spectra can be employed

**Figure 1** ¹⁹F NMR spectrum of the standard CFCl₃.**Figure 2** ¹⁹F NMR resonances of 3-trifluoromethylpyrazole at different temperatures.

to distinguish between species undergoing internal molecular dynamics between conformations: for example, at -130 °C, the two rotamers of the CFBr₂-CF₂Br molecule exhibit two different ¹⁹F chemical shifts and their ratio can be determined.

As an example of the scale of the temperature dependence of ¹⁹F chemical shifts, **Figure 2** shows the ¹⁹F resonance of 3-trifluoromethylpyrazole at different temperatures.

Effective Nuclear Charge Dependence of Fluorine Chemical Shifts

A good correlation between ^{19}F chemical shifts and electronegativity has been observed for the shielding in binary fluorides: it was found that for EF_n compounds ($\text{E} = \text{Se}, \text{As}, \text{Te}, \text{Sb}; n = 5 \text{ or } 6$) ^{19}F resonance frequencies increase with increasing electronegativity. The effect of electronegativity can also be illustrated by the changes of ^{19}F chemical shifts along the series $\text{CH}_n\text{F}_{4-n}$ and $\text{SiH}_n\text{F}_{4-n}$ as the value of n changes from 1 to 3 (Figure 3).

An opposite trend (i.e. the shielding increases with increasing electronegativity) has been found in the $\text{CF}_n\text{Cl}_{4-n}$ series: this is probably due to the greater +M (mesomeric) effect of F with respect to Cl.

Analogous simple correlations have also been reported between the ^{19}F chemical shifts of mixed silicon halides of the type $\text{SiF}_n\text{Y}_{4-n}$ ($\text{Y} = \text{Cl}$ or $\text{Br}; n = 1, 2 \text{ or } 3$) and the sum of the electronegativities of the substituents (Figure 4).

A similar pattern has been reported for the following pairs of compounds:

$$(\text{CF}_3)_2\text{O} \quad \delta(^{19}\text{F}) = -62 \text{ ppm}$$

$$(\text{CF}_3)_2\text{S} \quad \delta(^{19}\text{F}) = -39 \text{ ppm}$$

$$\text{CF}_3\text{CH}_2\text{Cl} \quad \delta(^{19}\text{F}) = -71 \text{ ppm}$$

$$\text{CF}_3\text{CH}_2\text{Br} \quad \delta(^{19}\text{F}) = -68 \text{ ppm}$$

$$\text{CF}_2\text{ClCH}_3 \quad \delta(^{19}\text{F}) = -45 \text{ ppm}$$

$$\text{CF}_2\text{BrCH}_3 \quad \delta(^{19}\text{F}) = -37 \text{ ppm}$$

It should always be borne in mind that ^{19}F shielding is controlled by paramagnetic and anisotropic terms to a greater extent with respect to the -I (inductive) effect of substituents.

Figure 3 Plot of $\delta(^{19}\text{F})$ against $\Sigma\chi$ (electronegativity of the substituents) for a series of monomeric compounds $\text{CH}_{3-n}\text{F}_n$ and $\text{SiH}_{3-n}\text{F}_n$.

The ^{19}F chemical shift is also dependent on the total charge: ^{19}F shielding decreases from the neutral to the anionic species; for example, $\sigma(\text{MF}_4) > \sigma(\text{MF}_6)^{2-}$ ($\text{M} = \text{Si}, \text{Ge}, \text{Sn}$) and also from neutral to cationic species $\sigma(\text{NF}_3) > \sigma(\text{NF}_4)^+$. In general, the shielding decreases with increasing number of fluorine atoms in the compound.

In poly- and perfluoroalkanes, the following simple relation (with some exceptions) has been found

$$\delta\text{CF}_3 > \delta\text{CF}_2 > \delta\text{CF}$$

which is completely the opposite of that found for ^1H NMR spectra of alkane derivatives.

It is worth noting that the order of ^{19}F chemical shifts in $\text{FC}\equiv\text{CCF}_3$ corresponds perfectly to the relative electron density of the two groups: the anomaly due to the anisotropy of the triple bond found in the ^1H NMR chemical shift of acetylene is not detected in fluorine resonance.

Substituent and Structure Dependence of Fluorine Chemical Shifts

The chemical shift of the CF_3 group in a series of 1,1,1,4,4,4-hexafluorobut-2-enes, such as those in Figure 5, clearly indicates that in compounds containing *trans*- CF_3 groups, $\delta(^{19}\text{F})$ is generally shifted to higher field with respect to isomers containing *cis*- CF_3 groups.

Geminal and *cis* and *trans* *vicinal* fluorine in molecules such as $\text{CF}_2=\text{CFH}$ also possess very different chemical shifts, the *geminal* (-185 ppm) being often the more shielded with respect to *cis* (-102 ppm) and *trans* (-129 ppm) *vicinal* ones.

Aromatic fluorine nuclei are more shielded with respect to perfluoroethylene derivatives, and shielding

Figure 4 Plot of $\delta(^{19}\text{F})$ against $\Sigma\chi$ (electronegativity of the substituents) for a series of monomeric compounds $\text{SiCl}_{3-n}\text{F}_n$.

Figure 5 $\delta(^{19}\text{F})$ for a series of hexafluorobut-2-enes.

Figure 6 Monofluorophenylplatinum(II) complexes.

generally increases with increasing substitution of H with F: for example, $\delta(^{19}\text{F})$ is -116 ppm for $\text{C}_6\text{H}_5\text{F}$, -139 ppm for $1,2\text{-C}_6\text{H}_4\text{F}_2$, and -163 ppm for C_6F_6 .

The ^{19}F chemical shift values of fluoroaromatic compounds can be used as a measure of the electronic interaction of ring substituents: for example, it has been shown that the 4-fluorine shift can be related to the π -electron donating or withdrawing properties of the substituent group X in pentafluoroaromatics.

Several studies carried out on monofluorophenylplatinum complexes like that in **Figure 6** gave information on the electronic character of the bond between the platinum and the anionic X ligand. By using a simple relationship between the shift of the 4-fluorine atom and the coupling constant between the 2- and 4-fluorine atoms it has been possible to determine empirically the extent of π -interaction in organometallic compounds.

The difference in the chemical shift of the 3- and 5-fluorine atoms and that of 4-fluorine in *trans*- $[(\text{Et}_3\text{P})_2\text{Pt}(\text{C}_6\text{F}_5)\text{X}]$ (where $\text{X} = \text{Me}, \text{Cl}, \text{Br}, \text{I}, \text{NO}_2, \text{NCS}, \text{CN}$ and ONO_2) derivatives has been used as a criterion of π -acceptor interaction. The π -bonding sequence resulted in the following order sequence, in accordance

with the *trans* effect:

The ^{19}F chemical shift can be also employed to investigate halide-exchange reactions: from the reaction of Me_3SbF_2 ($\delta = -106.1\text{ ppm}$) with Me_3SbCl_2 the mixed halide Me_3SbClF has been obtained ($\delta = -110.9\text{ ppm}$). Its ^{19}F chemical shift value is significantly different from that found for the starting reagent.

Anisotropy of Fluorine Chemical Shifts

In anisotropic media the fluorine chemical shift is strongly dependent on the orientation of the molecule with respect to magnetic field. This fact is very important because many systems widely investigated by ^{19}F NMR, for example biological matrices, are anisotropic media.

Coupling Constants

Coupling constants are very useful for discussing the structure and nature of chemical bonding in compounds containing fluorine. However, to date only a few relative signs of couplings have been reported, and it is not possible in all cases to establish with certainty the effect of the substituents and of the structure on the element-fluorine bond.

Coupling constants involving fluorine atoms are solvent and temperature dependent: for example, for the derivative ClF a difference of $\sim 85\text{ Hz}$ has been found for

$^1J(^{35}\text{Cl}, ^{19}\text{F})$ between the liquid and the gasphase. The differences are, in general, of the order of 0.1–10%. A dependence on temperature has been observed even when no conformational changes or exchange averaging processes are present. Several investigations, carried out on temperature coefficients of fluorine spin–spin coupling, indicated that these coefficients can have both signs and can even be as large as 2.3–2.4 Hz per °C.

One-Bond Couplings

Typical values of one-bond spin–spin coupling constants between ^{19}F and other nuclei $^1J(\text{X}, ^{19}\text{F})$ are reported in **Table 3**.

In binary fluorides, it has been shown that the reduced one-bond coupling constant $^1J(\text{X}, ^{19}\text{F})$ follows a periodic table trend; the value of $^1J(\text{X}, ^{19}\text{F})$ generally increases with increasing atomic number of X. The one-bond coupling constants between fluorine and metal atoms vary within a very large range; for example, the coupling between tungsten and fluorine is about 60–70 Hz, whereas that between platinum and fluoride groups ranges from 1100

Table 3 Magnitudes of some representative one-bond coupling constants, $^1J(\text{X}, ^{19}\text{F})$

to 2100 Hz. $^1J(\text{M}, ^{19}\text{F})$ depends strongly on the structure and coordination number of the metal atom M.

$^1J(^{13}\text{C}, ^{19}\text{F})$, generally negative, has a range centred at about 300 Hz and depends strongly on the nature and electronic properties of substituents. The one-bond coupling constants between phosphorus and fluorine have values between 500 and 1500 Hz. It is interesting to note that the $^1J(^{31}\text{P}, ^{19}\text{F})$ of RPF_2 groups generally decreases upon coordination to a metal: for example, in CF_3PF_2 the $^1J(^{31}\text{P}, ^{19}\text{F})$ is 1245 Hz, whereas in the complex $(\text{CF}_3\text{PF}_2)_2\text{Mo}(\text{CO})_4$ it is 1172 Hz. The $^1J(^{31}\text{P}, ^{19}\text{F})$ coupling constant can be used to distinguish axial and equatorial fluorinated groups in octahedral derivatives: for example, in the tetrafluoro(pentane-2,4-dionato)-phosphorus (V) derivative (**Figure 7**) which contains two sets of magnetically different fluorine atoms, the two coupling constants are 824 (axial) and 741 (equatorial) Hz, respectively.

The $^1J(^{29}\text{Si}, ^{19}\text{F})$ in silicon fluorides is dependent not only on temperature but also on the time-varying electric field, i.e. dispersion interactions, which alter the net electronic state of derivatives. The values of $^1J(^{29}\text{Si}, ^{19}\text{F})$ increase with increasing intermolecular dispersion interactions.

$^1J(^{11}\text{B}, ^{19}\text{F})$ coupling constants are generally very small and dependent on concentration and the nature of the solvent: for example, in acetonitrile the $^1J(^{11}\text{B}, ^{19}\text{F})$ for the BF_4 ion is 0.39 ± 0.07 Hz, whereas in water it is 1.07 Hz due to ion-pair formation.

Two-Bond Couplings

Typical values of two-bond spin–spin coupling $^2J(\text{E}-\text{X}-^{19}\text{F})$ are reported in **Table 4**. *Geminal* coupling constants $^2J(\text{E}-\text{X}-^{19}\text{F})$ are sensitive not only to the factors reported for the one-bond coupling, i.e. electronegativity, but also to the nature of the intervening atom X, to the F–X–E bond angle, and finally on the stereochemistry of the compound.

$^2J(^1\text{H}-\text{X}-^{19}\text{F})$ and $^2J(^{13}\text{C}-\text{X}-^{19}\text{F})$

Most of the data reported are for X=C. The $^2J(^1\text{H}-\text{X}-^{19}\text{F})$ are generally in the range 50–80 Hz. It is very

Figure 7 Fluorine coupling constants in tetrafluoro(pentane-2,4-dionato)phosphorus(V).

interesting to note that no significant difference has been observed between $^2J(^1\text{H}-\text{C}-^{19}\text{F})$ and $^2J(^1\text{H}-\text{N}-^{19}\text{F})$.

In methanes, $\text{HCFA}'\text{A}''$ (A' and A'' = alkyl, aryl, halides, etc.) a simple relationship (eqn [1]) between $^2J(^1\text{H}-\text{C}-^{19}\text{F})$ and the electronegativities $E_{\text{A}'}$ and $E_{\text{A}''}$ of A' and A'' substituents has been found on the basis of a large set of experimental data.

$$^2J(^1\text{H}-\text{C}-^{19}\text{F}) = 78.76 + 8.45E_{\text{A}'}E_{\text{A}''} - 16.73(E_{\text{A}'} + E_{\text{A}''}) \quad [1]$$

It has been possible to distinguish *cis*- and *trans*-1,2-difluoroethylene on the basis of their different *geminal* coupling constant values, the $^2J(^1\text{H}-\text{C}-^{19}\text{F})$ for the *trans* being greater than that for the *cis* isomer.

The $^2J(^{13}\text{C}-\text{X}-^{19}\text{F})$ are generally in the range 8–15 Hz and positive.

² $J(^{19}\text{F}-\text{X}-^{19}\text{F})$

Geminal coupling constants $^2J(^{19}\text{F}-\text{X}-^{19}\text{F})$ are very sensitive to hybridization of the intervening atom X and to the electronegativity of its substituents: the isotropic $^2J(^{19}\text{F}-\text{C}-^{19}\text{F})$ can range from <5 to 110 Hz for sp^2 carbon, and from ~100 to ~350 Hz for saturated carbon. In $\text{X}-\text{CF}_2-\text{CH}_2\text{F}$ and $\text{X}-\text{CF}_2-\text{CFYZ}$ derivatives (X, Y, Z = halide $\neq$ F), a relationship [2] has been found:

$$|^2J(^{19}\text{F}-\text{X}-^{19}\text{F})| = 135.3 - 5.95 \sum \chi_i \quad [2]$$

where χ_i = electronegativity.

Table 4 Magnitudes of some selected *geminal* coupling constants $^2J(\text{X}, ^{19}\text{F})$

Also, in olefinic compounds $\text{XYC}=\text{CF}_2$, the $^2J(^{19}\text{F}-\text{X}-^{19}\text{F})$ coupling constants are dependent on the nature of substituents. The magnitude of $^2J(^{19}\text{F}-\text{X}-^{19}\text{F})$ is ~50 Hz for X and Y = H or C, whereas values of more than 100 Hz have been observed when X and Y are metals such as Pt or Pd.

In compounds of the type $\text{F}_2\text{C}=\text{CXY}$, a linear correlation between F–F *geminal* coupling constants and fluorine chemical shift has been found. It has been ascribed to a change in the density of the nuclear spin information carrying electrons to the intervening carbon atom due to valence bond resonance structures such as $\text{F}_2\text{C}^+-\text{CF}=\text{CF}-\text{O}^-$.

The dependence of F–F *geminal* coupling constants on the F–C–F angle is very different from that of *geminal* H–H couplings: in fact, the latter increase monotonically with increasing H–C–H angle, whereas the former change markedly with F–C–F angles and have a minimum near 110° . This is due to the fact that the Fermi contact term (FC) is sensitive to F–C–F angle, whereas both the spin dipolar (SD) and orbital (OB) terms seem to be insensitive to the change of F–C–F angle.

Vicinal Couplings

Typical values of three-bond spin–spin coupling $^3J(\text{E}-\text{X}-\text{X}-^{19}\text{F})$ are reported in Table 5. They are dependent on the electronegativity of substituents, on the bond angle $\text{E}-\text{X}-\text{X}-^{19}\text{F}$, and also on the dihedral angle $\text{E}-\text{X}-\text{X}-^{19}\text{F}$.

Table 5 Magnitudes of some selected vicinal coupling constants $^3J(\text{X}, ^{19}\text{F})$

Compound	X	$^3J(\text{X}, ^{19}\text{F})/\text{Hz}$

From a comparison of proton–fluorine coupling constants and bond angles in a series of cyclic organic molecules, it has been found that $^3J(^1\text{H}, ^{19}\text{F})$ generally decreases as the H–C–C–F bond angle increases. In addition, the dihedral angle dependence of $^3J(^1\text{H}, ^{19}\text{F})$ is very similar to the dependence of $^3J(^1\text{H}, ^1\text{H})$, i.e. $(^1\text{H}, ^{19}\text{F})$ has a maximum value when the dihedral angle ϕ between H and F is 0° and 180° , and a minimum value when the dihedral angle is 90° . In olefinic compounds (for example the last six derivatives in **Table 5**) it has been found that $^3J(^1\text{H}, ^{19}\text{F})_{\text{cis}}$ is always smaller than $^3J(^1\text{H}, ^{19}\text{F})_{\text{trans}}$.

The angular dependence of *vicinal* F–F couplings on the ^{19}F –C–C– ^{19}F dihedral angle is very different from that reported for *vicinal* H–H couplings. Some theoretical studies have suggested that in *vicinal* F–F couplings, although the spin dipolar and orbital terms are a simple function of the dihedral angle ϕ , ^{19}F –C–C– ^{19}F , the Fermi contact term is a function which is strongly dependent on both substituents and ϕ . Therefore, for total *vicinal* F–F couplings (to which the Fermi contact term makes the most important contribution), it is very difficult to find clear relationships involving dihedral angles.

Long-Range Couplings

Long-range coupling constants have been found to be structurally and stereochemically dependent. $^4J(^{19}\text{F}, ^{19}\text{F})$ coupling constants can be much larger in magnitude than $^3J(^{19}\text{F}, ^{19}\text{F})$ and the values range from 0 to 200 Hz. The values of $^4J(^{19}\text{F}, ^{19}\text{F})$ are diagnostic in several saturated cyclic, unsaturated, and aromatic molecules. For example, from the spectra of *cis*- and *trans*-4H-perfluoromethylcyclohexane, both having an equatorial CF_3 group, the following $^4J(^{19}\text{F}, ^{19}\text{F})$ coupling constant values have been deduced:

$$^4J(^{19}\text{F}_{\text{eq}}, ^{19}\text{F}_{\text{eq}}) \approx 9 \text{ Hz}; \quad ^4J(^{19}\text{F}_{\text{eq}}, ^{19}\text{F}_{\text{ax}}) \approx 1 \text{ Hz}; \\ ^4J(^{19}\text{F}_{\text{ax}}, ^{19}\text{F}_{\text{ax}}) \approx 27 \text{ Hz}$$

$$^5J(^{19}\text{F}_{\text{C}}, ^{19}\text{F}_{\text{C}}) = 75 \text{ Hz}$$

Figure 8 The two conformational isomers of bis(ditrifluoromethyl)tetrachloroethane.

$^4J(^{19}\text{F}_{\text{ax}}, ^{19}\text{F}_{\text{ax}})$ values can be very large due to the through-space interactions of sterically close diaxial fluorine atoms. On the other hand, in aromatic fluorobenzene derivatives the $^4J(^{19}\text{F}, ^{19}\text{F})$ coupling constant provides only limited structural information: the $^3J(^{19}\text{F}, ^{19}\text{F})$, $^4J(^{19}\text{F}, ^{19}\text{F})$ and $^5J(^{19}\text{F}, ^{19}\text{F})$ coupling constants are often very similar and they can range from 18 to 20, 0 to 20 and 5 to 18 Hz, respectively.

A single large five-bond constant value (~ 75 Hz) has been observed for the conformationally gauche form of bis(ditrifluoromethyl)tetrachloroethane and it has been ascribed to the close proximity of the fluorines on the two trifluoromethyl groups (**Figure 8**).

In other cases, it has been proposed that some unusually large long-range couplings with the nuclei not in close spatial proximity are due to the connection of the fluorine by an intervening π network.

The $^nJ(^{19}\text{F}, ^{19}\text{F})$ coupling constant between the two fluorine atoms in compound I in **Figure 9** is exceptionally large. It is the highest value reported to date and it also exceeds three- and four-bond coupling constants. This has been attributed to the overlapping nonbonding electron distribution for two F nuclei in close spatial proximity which allows correlation not only of electron-pair bond to electron pair, but also of electron spin.

The $^nJ(^{19}\text{F}, ^{19}\text{F})$ coupling constant determined for other molecules containing the F–C=C–C=C–F moiety, in which coupling occurs through the s electrons, are nearly two orders of magnitude smaller; for example, $^5J(^{19}\text{F}, ^{19}\text{F})$ in $\text{CF}_2=\text{CH}-\text{CH}=\text{CF}_2$ is 35.7 Hz, and in compounds II and III in **Figure 9** it is 16.5 and 7.0 Hz, respectively.

In fluorofuranoses (for example compound IV in **Figure 9**), the ^{19}F chemical shift and the coupling constants often provide a means of assigning the stereochemistry: for example, 1α -F resonates to higher field with respect to 1β -F, the *cis* coupling to H2 is much smaller (4–6 Hz) than the corresponding *trans* coupling (20 Hz), and finally the *trans* coupling to H4 (4–8 Hz) is much larger than the *cis* one (1–2 Hz).

Figure 9 Long-range coupling constants in different compounds containing fluorine.

^{19}F Relaxation

Very few reports have been published on fluorine relaxation times: in most cases the results reported for several different molecules indicate that the spin rotation mechanism is dominant at higher temperatures, whereas the intermolecular dipole–dipole mechanism is not negligible at lower ones. The chemical shift anisotropy contribution can also be an important factor, whereas the intramolecular dipole–dipole mechanism and scalar coupling contribution seem to be negligible in ^{19}F relaxation. Some fluorine relaxation times (T_1 , T_2 and $T_{1\rho}$) have been used for establishing dynamics in a copolymer of tetrafluoroethene and hexafluoropropene.

Applications

The ever-increasing capabilities of NMR instruments and the high NMR sensitivity allow analytical applications of fluorine NMR to small and big molecules and relevant important information to be gained on chemicals, polymers, membranes, and intracellular environments. Such information is not readily available by other methods. For example, ^{19}F spectroscopy has proved to be useful within a large range of applications, from the study of various random and alternating copolymers of fluorosiloxane and hybrid fluorocarbon fluorosiloxane to the study of fluoro complexes of aluminium in aqueous solution and in zeolites. ^{19}F NMR has been applied to study the effect of plasticizers on LiCF_3SO_3 -containing polymer electrolytes and also to investigate the molecular structure of hydrogen-bonded clusters between F^- and $(\text{HF})_n$.

^{19}F NMR spectroscopy can be successfully applied to study relevant catalytic reactions: for example, the oxidative addition of $\text{C}_6\text{Cl}_2\text{F}_3\text{I}$ to $\text{Pd}(0)$ and the *cis*-to-*trans* isomerization (involved in the Stille reaction and other Pd-catalysed syntheses) have been investigated, and it has been shown that the isomerization of *trans*- $[\text{Pd}(\text{C}_6\text{Cl}_2\text{F}_3\text{I})(\text{PPh}_3)_2]$ follows a first-order law. A four-pathway mechanism for this isomerization has also been proposed on the basis of ^{19}F NMR kinetic study.

Several ^{19}F NMR studies have been reported on ligand exchange reactions of metal complexes (i.e. the $\text{Al}(\text{Tf}ac)_3$ - $\text{Al}(\text{bz}ac)_3$ system) and also on relative polarity and reactivity of N–H, N–Hg and N–Au bonds in intermolecular exchange reactions of fluorine-containing ligands (for example, 2-(4-fluoro-phenyl) benzimidazole) and their PhHg and Ph_3PAu derivatives.

Another interesting chemical application is the determination of the enantiomeric excesses of chiral acids by ^{19}F NMR of their esters derived from fluorine compounds.

Molecules containing fluorine that can be transported into cells can be employed as indicators for monitoring intracellular environments. ^{19}F NMR has been used to characterize drug–protein conjugates (immunogens) and to probe drug–protein binding. ^{19}F NMR spectroscopy has been shown to be a powerful technique for identifying metabolites of fluorine-containing drugs and for evaluating changes in the metabolism of fluoropyrimidines after the use of a biochemical modulator. This technique often allows a correlation between improved therapeutic response and the biochemical effects generated in tissues. For example, in the monitoring of *in vivo* tumour metabolism, after biochemical modulation of 5-fluorouracil by the uridine phosphorylase inhibitor 5-benzylacyclouridine, analysis of the NMR data

revealed an increased formation and retention of fluorouracil nucleotides and fluorouridine in colon tumours treated with the regimen containing 5-benzylacyclouridine, and a reduction in 5-fluorouracil catabolites.

Food and Dairy Products, Applications of Atomic Spectroscopy

NJ Miller-Ihli and SA Baker, U.S. Department of Agriculture, Beltsville, MD, USA

Published by Elsevier Ltd.

This article is reproduced from the previous edition, volume 1, pp 583–592.

Food composition data are critical for consumers and health care professionals to make choices and recommendations based on the nutrient content of foods. Trace elements contribute significantly to human health with 25 elements identified as being of interest. A review of the nutrients for which recommended daily allowances (RDAs) exist shows that 7 of 19 are minerals (Ca, Fe, I, Mg, P, Se, and Zn). In addition, the National Research Council has established estimated safe and adequate daily dietary intakes (ESADDIs) rather than RDAs for an additional five elements (Cr, Cu, F, Mn, and Mo) and three electrolytes (Cl, K, and Na) have been identified as essential. Ten additional trace elements are considered essential but no human requirement level has been set for them: As, Ni, Si, B, Cd, Pb, Li, Sn, V, and Co. The status of fluorine as an essential nutrient has been debated and conflicting data exist but its valuable effects on dental health certainly make it of potential interest.

Reviews of the state of knowledge of food composition data show that there is a significant lack of data for specific food groups and for several of the elements of interest, including the seven for which RDAs have been identified. This is owing, in large part, to the lack of suitable analytical methodology, which is why rugged, accurate methods are needed that use modern analytical methodology and instrumentation. Health professionals and the public are increasingly interested in the maintenance or promotion of good health and disease prevention, rather than the diagnosis and cure of diseases. Clearly good nutrition is an important part of good health so nutritionists need high quality food composition data so that they can assess the nutrient content of foods consumed. Reviews of food composition data still suggest the mineral composition of foods is not well characterized despite the extensive data found in U.S. Department of Agriculture's Nutrient Data Base for Standard Reference SR-12 (the former USDA Handbook 8). In addition, there is now interest in knowing the exact chemical form of the trace elements in foods since not all forms are biologically active.

Another issue which highlights the importance of continued research for methods for trace elements in foods and beverages is related to the Nutrition Labelling and Education Act of 1990 (NLEA); this is now a law in the United States and provides nutritional information to the consumer. Fifteen mandatory nutrients must be listed

on the labels, including three trace elements (Ca, Fe, and Na). Thirty-four additional 'voluntary' nutrients which affect human health may be required in the future and 12 of those are trace elements (K, P, Mg, Zn, I, Se, Cu, Mn, F, Cr, Mo and Cl).

Typically, essential elements have been at sufficiently high concentrations that, with the introduction of graphite furnace atomic absorption spectroscopy (GFAAS) more than three decades ago, detectability is not an issue. Researchers are interested in 'new' low-level trace elements with known or potential nutritional impact, which are present at lower concentrations and, because of potential interferences in GFAAS, it has been found that inductively coupled plasma mass spectrometry (ICP-MS) coupled with graphite furnace/electrothermal vaporization (ETV-ICP-MS) provides superior detectability. The most often utilized instrumentation for generation of food composition data includes: atomic absorption spectroscopy [flame (FAAS) and graphite furnace (GFAAS)]; flame atomic emission spectroscopy (Na, K); inductively coupled plasma atomic emission spectroscopy (ICP-AES) and ICP-MS.

In this article, the description of applications will highlight the selection of the instrumentation used as well as the sample preparation methods (often the most critical part of a complete analytical method). Calibration strategies will be discussed and any specialized interference effects will be highlighted. Strategies for validating and facilitating technology transfer of the methods will also be discussed and the need for commercial as well as in-house reference materials will be featured.

Sampling (Sample Collection and Processing)

One of the most overlooked aspects of analytical determinations relates to the suitability of the sample provided for analyses. If food composition data are being generated, it is very important to know if interest lies with the specific sample at hand or if that sample is supposed to be representative of a larger bulk sample (e.g. 1 jar from a lot totalling 100 000 jars). Work completed in the Food Composition Laboratory (USDA, Beltsville Human Nutrition Research Center, Beltsville, MD) is often in support of the Nutrient Data Laboratory

which is responsible for the publication of the U.S. Department of Agriculture's Nutrient Data Base for Standard Reference SR-12 (formerly known as Handbook 8) which is the primary US database for food composition data. This is now available online and can be searched (see <http://www.nal.usda.gov/fnic/foodcomp/search>). As such, the goal is to include data representative of the national US food supply. Because large-scale national sampling is too expensive, samples are often obtained nationwide (if possible) and brands are selected on the basis of popularity (consumption) to try to gain representative samples for analysis. Samples are typically brought into the laboratory and, depending on the form of the sample, a decision is made either to analyse multiple samples or to composite and homogenize the whole of the material (if possible) and to remove separate sample aliquots. Most often, a preliminary evaluation of the homogeneity of a selected number of analytes in the material serves as a basis to select the sample size and number of replicate samples to be analysed.

Tools are available which facilitate sample homogenization without trace element contamination and equipment that is not available commercially can often be custom made. To dissect meat, titanium blade knives or high purity glass knives may be appropriate. Large-scale mixers (e.g. Robot-Coupe, Jackson, MS) equipped with a plastic-lined bowl and titanium blades to avoid possible contamination from the stainless steel apparatus have been used successfully to blend both common samples and a diet reference material (RM8431) sold by the National Institute of Standards and Technology (NIST, Gaithersburg, MD). Polythene trays and polypropylene storage containers are most often used without risk of contamination. An assessment of contamination risk is summarized in Table 1 and 2. Table 1 lists those elements prone to contamination while highlighting common sources of contamination. Table 2 contains a list of materials (from most preferable to least) for use during sample preparation for trace element determinations. To further minimize the likelihood of contamination [particularly for low temperature (≤ 85 – 95 °C) wet ash preparations] glassware can be silanized; the coating will be retained on the surface of the glassware up to temperatures of approximately 350 °C, providing excellent protection from contaminants leached from the glassware owing to matrix interaction with the glass. In addition, silanization prevents loss of analyte due to adsorption on the container walls.

Contamination control, in a general sense, is not difficult and common sense can often provide protection from sample contamination, especially during the early sample handling stage. In an ideal world, samples are processed in clean rooms (e.g. class 100 clean room) designed to have minimal contamination because the air is filtered through hepa filters. Clean hoods and laminar

Table 1 Trace element determinations – risk assessment

<i>Contamination potential</i>	
High potential	Al, Ca, Cr, Cu, Fe, Pb, Sn, Zn
Medium potential	Co, K, Mn, Mo, Na, Ni, V
Low potential	Mg, Se
<i>Sources of contamination</i>	
Glass	Al, Ca, Co, Cr, Cu, Fe, K, Mg, Na
Porcelain	Al, Cu, K, Na, V
Rubber	Co, Cu, Fe, Zn, Sn
Building materials	Al, Ca, Mg
Stainless steel	Co, Cr, Cu, Fe, Mn, Ni, Zn
Cosmetics	Fe, Pb, Zn, Cu
Skin	K, Na, Ni, Cu, Fe
Smoke	Fe, Pb, K, Ni
Haemolysis	Ca, Co, Cu, Fe, K, Mg, Mn, Zn

Table 2 Sample container materials

<i>Material</i>	
Teflon	Most desirable (least trace element contamination)
PFA	
FEP	
Tefzel	
Polyethylene	
Polypropylene	↓
Quartz	
Platinum	
Borosilicate glass	
	Least desirable

air flow units can also prove useful, as well as wearing clothing that minimizes particulate generation, selecting powder-free gloves, taking care in cleaning glassware and plasticware with dilute, high purity acid, and covering gas cylinders which may be delivered coated with rust and peeling paint.

Sample Preparation (Reagents and Ashing Methods)

One of the most important means of avoiding unnecessary risk for trace element contamination is the judicious selection of reagents for sample preparation. Sub-boiling distilled or double-distilled acid is a good choice for sample treatment. As an example, Pb contaminant concentrations found in nitric acid (65–70% v/v) ranged from <1 part per trillion (ppt) for sub-boiling distilled to 0.3 ppb for commercial 'high' purity acid. Although ppb levels may be suitable in many instances, sub-boiling distilled nitric acid (Seastar Chemicals, Sidney, British Columbia) provides even lower blanks with levels of <50 ppt for Ca; <20 ppt Fe and K; <10 ppt Cr, Cu, Na, Mg, Ni, Sn, Zn; and <1 ppt for Cd, Mn, and V, and is therefore highly recommended for ultratrace analyses.

Of course all reagents used throughout the course of any analyses provide potential sources of contamination

and must be evaluated. Hydrogen peroxide comes in different levels of purity and some types prove to be particularly problematic for only a select number of elements. In the past, unacceptably high Cr levels have often been found. A peroxide called Perone (DuPont, Wilmington, DE), made for the semiconductor industry, has been evaluated in several laboratories and proved suitable for any number of elements (including Mn, Cu, Zn, Fe, Cr, and Co). Unfortunately this is not sold in small enough quantities to be suitable for the typical analytical laboratory. For analysts using matrix modifiers for GFAAS, the modifier can provide a significant level of contamination, indicating that very high purity materials should be used.

In all instances, environmental considerations are equally as important as reagent purity, when selecting a sample preparation method. In an ideal situation, samples can be handled under clean air conditions under laminar flow to prevent contamination. Potential sources of environmental contamination include the analyst (particles from skin or clothing), sample container material, air, gloves, heating block, muffle furnace, etc.

The two most common ashing procedures for food analyses are wet ashing and dry ashing procedures. Wet ashing may be done using a typical hot plate or heating blocks or it may be done using microwaves under increased pressure. Many modern microwave systems are now under temperature and pressure control and various methods are available in the literature. In a laboratory which processes many samples with one matrix type, microwave digestion can be quite useful. If, however, the matrices are variable, experiment design requires that samples of similar type be put in the microwave together. Otherwise, depending on the carbohydrate content, pressure will build up in the samples at different rates, requiring venting which can be problematic if the microwave system does not have temperature and pressure monitoring control for each vessel. Another great benefit is the use of microwave digestion as a reference to compare with wet ashing results. The microwave system provides the benefit of increased pressure, ensuring almost complete digestion (depending on the sample matrix). When used under optimum conditions, microwave digests provide a reliable dissolution of samples and minimize the risk of sample contamination while saving significant time. Microwave sample digestion has been very much a growing field and the number of analysts using this sample preparation tool probably increased 10-fold between 1993 and 1998, for example.

Method Selection and Method Validation

Several factors should be considered in selecting the appropriate sample preparation and instrumental

detection method for a particular set of analyses. Factors include detection capability, ease of use, availability of instrumentation, time, cost, etc. One must consider the relative importance of the factors for their application but, most often, detection capability is the top priority. A good general rule is to use the simplest method possible that meets the analysis requirements. For example, if asked to determine Mn, Cu, and Zn in soft drinks, analysts should check to see if it could be carried out with a simple dilution directly using FAAS or simultaneous multielement ICP-AES (for greater speed). Once a method is selected it should be validated using one or more of the following strategies: (1) analysis of one or more standard reference materials; (2) comparison of results using an alternative method; (3) comparison of results with those from another laboratory; and (4) thorough evaluation of possible matrix interference effects (compare direct calibration with the method of additions). **Table 3** contains a list of commercial reference materials with matrices suitable for food and beverages analyses. One unfortunate aspect of solid commercial materials is that they are almost all freeze-dried and this is not a realistic representation of typical samples (e.g. meats, vegetables, fruits, etc.); analysts prefer to analyse 'as received'. Because these primary controls are so expensive, analysts should consider developing secondary, in-house controls that represent the food type/matrices most often analysed in their laboratory. These materials can be characterized using all the validation strategies listed above, with the assistance of colleagues and by using alternative methods.

Instrumentation and Applications

The literature is the most informative source of insights on how to select the most appropriate sample preparation methods and instrumentation to make accurate and precise trace element determinations. Analysts worldwide are continuously publishing their successes (and often their failures), allowing their colleagues to benefit from their experiences. Since the bulk of trace element determinations for foods and biological samples are done by a handful of techniques, four methods represent 98% of all determinations: (1) flame atomic absorption spectroscopy (FAAS); (2) graphite furnace atomic absorption spectroscopy (GFAAS); (3) inductively coupled plasma atomic emission spectroscopy (ICP-AES); and (4) ICP-mass spectrometry (ICP-MS). Comments on both the sample preparation method and the instrumentation are available to the reader. It is often a good idea to combine the best portions of several different methods when developing a method, and it is always good to avoid mistakes documented by others.

FAAS and GFAAS

An estimated 80% of all currently available trace element food composition data are the result of FAAS analyses after either wet ashing or dry ashing sample pretreatment. FAAS is a simple, robust, and easy to implement tool for the analysis of digests, and calibration can typically be accomplished using aqueous standards. Detection limits are in the sub-ppm range, making this method suitable for a wide range of elements (including Ca, Cu, Fe, Mg, Mn, Zn) in various sample matrices. Please note that Na and K are most often determined using flame emission spectroscopy rather than absorption on an AAS system.

GFAAS provides sub-ppb detection capability with μL -sized sample injections into a platform-containing graphite tube which is resistively heated to high (e.g. 2700°C) temperatures for sample atomization. In the 1990s, so-called STPF (stabilized temperature platform furnace) conditions established by Slavin were almost universally adopted. STPF conditions call for the use of (1) platform atomization, (2) matrix modification, (3) rapid heating ($1500^\circ\text{C s}^{-1}$ or more), (4) pyrolytically coated tubes, (5) fast digital electronics, (6) integrated absorbance measurements (peak area), (7) argon (stop-flow during atomization), and (8) Zeeman (or Smith-Hieftje) background correction. Methods developed with these criteria in mind will facilitate straightforward quantitation using aqueous standards to make external calibration curves, in most cases minimizing matrix interference effects and reducing the need for using the method of additions. Analytical figures of importance include sensitivity/characteristic mass, detection limit, accuracy, and precision.

The field of trace element analyses in nutrition is one of the most interesting areas. Trace elements serve as structural components of enzymes, vitamins, hormones, and protein-containing tissues. The trace element selenium helps in the defense mechanism against diseases and environmental risk. Selenium is the most promising trace element potentially involved in immune responses. Chromium is a cofactor for several enzyme systems, and is required for insulin receptor interaction. Consequently, research was conducted using FAAS to assess the Se and Cr content of eight food categories (cereals, beans, vegetables, greens, fruit, condiments and spices, dried fruits, and edible flowers). Samples were wet ashed using a combination of three acids and samples were analysed using FAAS at 196 nm (Se) and 425 nm (Cr) using an air-acetylene flame. A total of 190 samples were analysed and from the study it was concluded that dried fruits have the highest Cr content ($15\text{--}43.5\ \mu\text{g per } 100\ \text{g}$) and that beans have the highest Se content ($48.7\text{--}02.5\ \mu\text{g per } 100\ \text{g}$). FAAS also recently proved useful in the monitoring of Pb in dinnerware where excess levels can provide

increased risk to fetuses, children, and adults. A total of 0.9% of imported ceramic dinnerware and 2.5% of domestic ceramic dinnerware, evaluated over the course of 2 months in 1992, had levels in excess of the 3 ppm allowed limit for plates, saucers, and flatware. This work involved the use of Association of Official Analytical Chemists Official Method 973.32. FAAS was used by scientists at Behrend College (Erie, PA) to evaluate stainless steel cookware as a significant source of Ni, Cr, and Fe for ingestion. Nickel ingestion is potentially dangerous since Ni is implicated with health problems related to allergic dermatitis. Conversely, Cr and Fe are essential nutrients and stainless steel (typically 18% Cr, 8% Ni and 70–73% Fe) may provide a significant source. Sample preparation involved the addition of 5% acetic acid (Fisher), both cold and boiled, in each vessel for 5 min. Next, the acetic acid was analysed using FAAS and the manufacturers' standard conditions. Measurable levels of all three elements were determined with only Ni being high enough (0.0–0.1 mg Ni per day) to pose a health threat, leading to a recommendation that Ni-sensitive patients avoid stainless steel cookware and that the industry switch to a non-Ni formulation.

As evidenced by the previous examples, FAAS is a powerful technique but it may not always provide the necessary sensitivity for the determination of trace elements present at extremely low concentrations. This became apparent when the Swedish National Food Administration set out to develop a method for the determination of Pb, Cd, Zn, Cu, Fe, Cr, and Ni in dry foodstuffs after dry ashing at 450°C . Realising that contamination with elements such as Pb, Cr and Ni is probable, care was taken to acid-wash all plasticware associated with the analyses. FAAS was selected for Zn (213.9 nm air-acetylene, oxidizing), Cu (324.7 nm air-acetylene, oxidizing), and Fe (Fe 248.3 nm nitrous oxide-acetylene, oxidizing). Owing to the lower concentrations, GFAAS was used for Pb, Cd, Cr and Ni. Conditions were optimized based on the use of the appropriate resonance line but no one set of instrumental conditions proved acceptable for all four elements. Lead was analysed using platform atomization while Cd was measured in an uncoated tube and Cr and Ni were measured in a standard pyrolytic tube. Unfortunately, not using STPF conditions limited the capabilities of the method and the method of additions was required by most collaborating laboratories to get reasonably accurate results.

GFAAS serves as an excellent method for the direct determination of Pb in degassed cola beverages. Recent reports indicate, however, that GFAAS analyses of cola diluted with a solution of lanthanum to reduce chlorides and other matrix interferences required the use of the method of additions to obtain accurate results. If the

authors had done *in situ* oxygen ashing, and used Pd or Pd combined with magnesium nitrate as a matrix modifier, all matrix interference effects could have been removed. It is likely that the biggest problem with the background was owing to the sugar (carbon) which could have been removed during the thermal pretreatment step using oxygen ashing – permitting the use of aqueous calibration standards rather than requiring the method of additions. Sugars and syrups have been analysed directly after diluting ~1 g of sugar per 10 mL 5% nitric acid and using oxygen ashing in the thermal pretreatment step. Instrumental GFAAS detection limits (DL) were 10 pg, corresponding to a method DL of 0.9 ng g^{-1} . Researchers often use ingenious approaches to improve GFAAS performance. This was the case when developing a strategy for the determination of La in food and water samples. The problem is that La has a strong affinity for the graphite, leading to carbide formation and memory effects. Although the graphite has been improved to reduce this, lining the tube with tantalum or tungsten foil can eliminate physical contact with the graphite and lead to increased sensitivity. The tungsten-lined tube provided a detection limit of 7.8 ng and a characteristic mass of 8.1 ng for La. Precisions were better than 10% RSD and the average accuracy was $90 \pm 10\%$. GFAAS has been used by researchers at the US Food and Drug Administration to successfully determine Se in infant and enteral formulas. The method utilizes sample digestion on a hotplate after addition of magnesium nitrate–nitric acid. Following heating, digests were evaporated to dryness and placed in a 500°C muffle for 30 min to complete ashing. All Se is converted into Se^{4+} by dissolving the ash in HCl (5:1) and holding the solution at 60°C for 20 min. The Se^{4+} was subsequently reduced to Se^0 with ascorbic acid and collected on a membrane filter which was digested in nitric acid using microwave digestion. Following digestion and dilution, Se was determined using GFAAS. The recovery range for Se was 85–127% and analysed reference materials fell within the certified range for Se. The work was performed on a commercial system equipped with only a deuterium background correction. Peak height and peak area measurements both provided accurate results when using nickel nitrate for matrix modification. Finally, GFAAS has proved useful for the determination of Cr and Mo in medical foods. Both wet ashing and dry ashing proved acceptable and the detection limits were 0.24 ng mL^{-1} for Cr and 0.67 ng mL^{-1} for Mo. Both elements could be determined directly off the shelf and neither required the use of a matrix modifier. Optimum ashing temperatures of 1650 and 1600°C were found for Mo and Cr, respectively. The ideal atomization temperatures were 2400 and 2650°C , respectively, and all standard reference materials analysed provided results within the certified concentration range.

ICP-AES and ICP-MS

To assist consumers in maintaining healthy dietary practices and to assure product safety, the Nutrition Labelling Education Act (NLEA) was published in 1990 and the compliance deadline was May 1994. More than 17 000 food companies were affected by NLEA and labels for more than 250 000 products required modification. As such, Perkin-Elmer researchers developed a multi-element ICP-AES method using an axially viewed plasma which they coupled with microwave sample digestion. ICP-AES measurements allowed both trace and macro elements to be determined simultaneously owing to the wide linear dynamic range. In contrast to many official methods, which are analyte and/or matrix specific, and which often require multiple dilutions, this ICP-AES method gives multielement data (seven elements; nine wavelengths), providing an elemental fingerprint which proves useful in adulteration and/or contamination studies. Measurements were made on a Perkin-Elmer Optima [echelle polychromator with a segmented array charge coupled detector (SCD) equipped with a standard torch, a Scott spray chamber, and a crossflow nebulizer]. Although only a single 10 ppm multielement standard was successfully used for calibration, the use of three or more standards is recommended to cover such a large range. The use of duplicate wavelengths for Ca and Mg, combined with spike recovery checks, assisted with method validation. Literature reports highlighted the benefit of the Multiwave (Perkin-Elmer, Norwalk, CT) microwave system which provides pressure monitoring in each vessel, allowing different sample types to be digested together. Simultaneous multielement ICP-AES provides significant time-savings and the establishment of compromise conditions does not typically lead to significant deterioration of performance as compared with single element determinations.

In the 1990s, ICP-MS determinations have started to play a significant role in generation of food composition data. This technique provides multielement isotopic data with sub-ppb detection limits with the same convenience as flame AAS or ICP-AES and it is much faster than GFAAS. As interest in low level trace element concentrations continues to grow, more data are generated by ICP-MS and often alternative methods are employed to validate the ICP-MS method and resultant data. Such was the case in the study of Pb in green vegetables where GFAAS (dry ashing) and isotope dilution-ICP-MS (ID-ICP-MS) (wet ashing) were both used. The end result was comparable detectability and accuracy for in-house and commercial control materials. The limit of detection for Pb was $1\text{--}3 \mu\text{g kg}^{-1}$ and precisions ranged from 6% RSD for kale containing $500 \mu\text{g kg}^{-1}$ Pb to 20% RSD for cabbage containing $3 \mu\text{g kg}^{-1}$ Pb. These methods were used for a four-year study of Pb levels in green

vegetables with good success. Another advantage of ICP-MS is that it provides excellent detection capability for non-metals of nutritional interest, including P and I. Methods for I have typically been dependent on radio-iodide measurements and the specialized equipment required is not widely available. In contrast, ICP-MS allows the direct determination of I in solution using highly sensitive, specific, and interference-free detection of monoisotopic iodine (^{127}I). Samples were wet ashed in closed steel bombs using a mixture of nitric and perchloric acids which converted any volatile I species into non-volatile species. The concentrations measured were in the range $0.15\text{--}4.59\ \mu\text{g g}^{-1}$ (dry mass) and the detection limit was $30\ \text{ng g}^{-1}$ (dry mass) for a 0.5 g (dry) sample diluted to a final volume of 20 mL. The importance of ICP-MS in food analysis is growing but probably won't be fully realized until the list of the mandatory nutrients for labelling has been expanded.

Food and Nutritional Sciences

Within food science one studies all stages between primary agricultural food production up to consumption. Thus, one finds food scientists concerned with harvesting and slaughtering, subsequent preservation of crops and meat, transport, manufacturing of food products and meals, and their sensorial appreciation by consumers. Usually, nutrition is considered as a distinct field, where one specifically studies the role of food in sustaining the health of consumers. Both food and nutritional science are applied sciences that involve concepts of physics, chemistry, biology, and even psychology and sociology. Also, more technological disciplines are involved such as logistics and engineering. Typically, this overwhelming array of scientific areas is aggregated into subdisciplines such as food chemistry, food physics, food safety, food preservation, food engineering, food packaging, and sensory analysis.

Progress within the food and nutritional sciences has always been strongly dependent on experimentation and measurement for hypothesis generation and testing. Within the food sciences one can identify the need for three types of information: food composition, the meso- and microstructural arrangements in foods, and the sensorial impact of foods on the consumer. Within the area of nutrition one mostly requires information on the biological impact of foods. These information needs and the associated research questions are schematically depicted in

Figure 1 Overview of the three main application areas of magnetic resonance in food and nutritional sciences.

Figure 1. Within the realm of measurement technologies that is applied in food science and nutrition, magnetic resonance takes a unique position since it can be deployed to deliver information in all of the aforementioned areas. A particular strength of the magnetic resonance methods lies in their noninvasive and nonperturbing nature, which makes them suitable for real-time and *in situ* measurements. This is of particular advantage for *in vivo* measurements, and also for assessment of phenomena that occur during processing and storage of food products. Furthermore, within both food and nutritional science, a shift from hypothesis testing toward hypothesis generation is witnessed. This has become particularly apparent within the emerging 'omics' life sciences. Such approaches can only be successful when measurement technologies that are not particularly biased by prior expectations are available. Also, here magnetic resonance, and in particular NMR, has established itself a position due to its comprehensiveness and unbiased nature. The versatility of magnetic resonance in addressing challenges in the food and nutritional sciences is reflected in the range of techniques that is deployed. **Table 1** gives an overview of the different NMR-sensitive nuclei that are commonly studied in food science applications. For many applications magnetic fields generated by permanent magnets are sufficient, but often the investments in high-field superconducting magnets can also be justified. Within the next sections the three major applications areas of magnetic resonance will be reviewed, with particular emphasis on approaches for hypothesis generation and testing. Although the emphasis will lie on magnetic resonance developments within food and nutritional sciences, spin-offs

³¹ P	Phospholipids, phytates, inorganic phosphates	Colloidal phosphate in dairy, structures in meat products

to technological fields such as quality and process control will also be mentioned.

Food Composition

Analytical NMR

Food science was one of the first areas to recognize the analytical potential of magnetic resonance, in particular when it concerns high-field NMR. One can roughly discern three application areas of magnetic resonance in food compositional analysis (**Figure 2**). The unbiased nature of NMR is convincingly exploited in compositional profiling where large numbers of compounds, known or unknown, need to be detected and semi-quantified. The ability of NMR to produce detailed structural information can be exploited for identification of unknown, but relevant, compounds. Finally, magnetic resonance can be deployed for target analysis, that is, the detection and quantification of known compounds.

Compositional Differences and Similarities

Questions relating to compositional differences and similarities are quite common in food science. Fruits and vegetables, for example, contain many secondary plant metabolites that are known to determine taste and flavor, and are also associated with many health benefits. In many cases, one does not have a clear definition of the compounds of interest, and this is where the unbiased nature of NMR is a particular advantage. By recording comprehensive compositional NMR profiles one can

assess effects of agricultural production and harvesting, storage, and processing on the overall food compositions. Another important application is the determination of authenticity of foods. This is a particular issue where biological or geographical origin, often in combination with artisanal manufacturing has added significant value to food products. Typical examples are meat, fish, vegetable and fish oils, honey, fruits and their juices, and also manufactured products such as syrups, tea, coffees, wines, beers and liquors. The authenticity of such food ingredients and products can often not be captured in a single or a few known compounds, but is typically the result of the presence of many molecular species, of which many are not known. Their measurement represents an analytical challenge that can be well addressed by NMR. Another application area concerns so-called substantial equivalence testing of food products that are produced by genetically modified (GM) plants. The use of GM cultivars has sparked some controversy, in particular concerning limitations to assess potential negative ramifications of genetic manipulations. One aspect of the debate is concerned with unexpected, potentially undesirable changes in secondary metabolite levels in GM cultivars. The comprehensive and unbiased nature of NMR profiling is a unique advantage for detecting such changes.

Currently, most profiling studies are carried using ^1H NMR, at Larmor frequencies between 400 and 600 MHz, but ^{13}C and ^{31}P NMR have also been used for this purpose (**Table 1**). Most often, dissolved or extracted samples are measured by liquid-state NMR, but in several cases the use of semisolid-state ^1H HRMAS has also

Figure 2 Overview of research areas where magnetic resonance can be deployed to assess food compositions.

been applied to intact food materials. More specific information can be obtained from NMR spectra of natural abundance NMR-active isotopes. Such spectra can reveal isotope distributions that are very specific for biosynthetic origin, and can be used to assess geographical and biological authenticity of, for example, oils and beverages. In this respect, the use of ^2H NMR has been particularly useful, and has been coined as site-specific natural isotope fractionation (SNIF[®])-NMR. In several cases SNIF[®]-NMR has become the method of choice for detection of adulteration of food products with synthetic ingredients such as flavors, sugars, and alcohols.

The overwhelming amount of compositional information that is contained in high-field NMR profiles of foods can mostly only be interpreted using multivariate pattern recognition methods. The combination of compositional profiling by high-field NMR and multivariate analysis has become common practice for many food products, and has in some cases also been adopted by regulatory bodies as a preferred analytical method for sustaining claims on geographical and biological origin or manufacturing.

Identification of Relevant Compounds

An ever recurring question in studies concerning the composition of food materials is which chemical species are present. Such questions typically follow the aforementioned profiling studies where differences and similarities in food compositions are detected. Other drivers for identification of compounds are studies regarding biological activity and quality of food products and ingredients. In its most direct form, biological activity is assessed *in vivo* in humans, but due to cost and ethical considerations there is a strong drive for *in vitro* assays in the earlier research stages. Many of these *in vitro* assays involve cumbersome biological methods, but ESR has been particularly useful for rapid instrumental assessment of antioxidant capacity of complex natural extracts and their constituents. Within most foods, the identification of active compounds often resembles the challenge of finding a needle in a haystack. This has been addressed by identification strategies that are typically based on *in vitro* assay guided separations. The hyphenation of liquid chromatography and NMR in LC-NMR has in turn now been combined with other separation and detection methods. The combination with solid-phase extraction (SPE) recently culminated in LC-SPE-NMR. The deployment of SPE was effective in overcoming several limitations of LC-NMR such as poor sensitivity and solvent incompatibility. Further enhancement of sensitivity of the NMR experiment can be gained using cryogenic and capillary probe-head technologies. As in LC-SPE-NMR-MS, the combination of spectral

information from NMR and MS allows for the unambiguous *de novo* structural elucidation and identification of complex compounds. For many natural compounds, their NMR and MS spectral features have been recorded in databases, together with their bioactivities. These databases are actively exploited in the so-called process of dereplication where in bioactive mixtures one can recognize and eliminate from consideration those 'replicate' compounds for which structure and activity have already been described.

Quantitative Target Analysis

In comparison to other quantitative target analysis methods, such as chromatography, NMR is handicapped by the relatively high cost of equipment. NMR can in many cases still be operated effectively for target analysis when elaborate sample preparation steps can be circumvented or when a wealth of information can be provided on specific species. ^1H and ^{13}C NMR are being used for rapid quantification of lipids and their derivatives. ^{31}P NMR has established itself as a rapid and convenient means to quantify phosphorous-containing species such as lecithins and phytic acid in food ingredients. The capability of NMR for target analysis is complemented by the use of electron spin resonance to detect long-living radicals in foods. This is relevant for understanding the role of radical-mediated deterioration of food quality, as is, for example, the case in lipid oxidation (formation of rancidity) and loss of vitamins, flavor, and color. The detection of long-living radicals by ESR has also been used to detect nonpermitted use of γ -radiation of foods to enhance shelf-life of foods. When operated on benchtop equipment, NMR relaxometry, sometimes in combination with diffusometry, offers a convenient and noninvasive means to assess oil and water content in foods. Here, the combination of ease-of-use, relatively low-cost equipment, and the circumvention of laborious sample treatment methods makes NMR competitive to more conventional target analysis methods. Proof-of-principle studies have shown that handheld NMR devices can also be used for assessment of food compositions in a noninvasive manner.

Food Structure

Structural Organization in Foods

Within the domain of food structure one seeks to unravel the structural organization and dynamics of components in foodstuffs. This represents a challenge due to the large range of distance and timescales that are involved. A relatively simple example is given in **Figure 3(a)** where the different (length) scales of structural organization in cereals are represented. The starch in cereal

Figure 3 Overview of length scales that can be encountered in cereal materials and products. (a) Cereals as an example of food materials with structure and dynamics occurring at different length scales. (b) Operational ranges of magnetic resonance spectroscopy and imaging methods.

kernels such as wheat and rice is, for example, organized in starch granules that contain amorphous regions as well as domains where the starch chains are organized into helical structures. All these structural levels are of relevance when cereals are processed into edible foods, as is, for example, the case in rice cooking or the preparation of dough and finally bread. Within food science an array of spectroscopic and microscopic techniques is deployed, but as is shown in **Figure 3(b)**, NMR distinguishes itself by covering virtually all length scales and by its ability to assess dynamic events, particularly those involving water, in a noninvasive manner.

Molecular Structure of Food Lipids and Biopolymers

Proteins, carbohydrates, and lipids not only serve as important nutrients but are also important for giving foodstuffs their typical and appreciated textures. Carbohydrate polymers such as pectins, carrageenans, and gums are widely used as structuring agents. Biopolymers also play an important role in making other nutrients bioavailable. Milk proteins, for example, act as carriers for calcium and phosphate. One-dimensional ^1H and ^{13}C liquid NMR are straightforward and established tools for determining the primary structure of biopolymers, that is, their monomer composition. Through-bond and through-space interactions as provided by 2D NMR experiments have been used for elucidating secondary and tertiary molecular structures.

The Structural Role of Water

For many food products, water is critical to establish food quality. Texture, microbial status, processability, and digestibility are all determined by interaction of water with food components. The interaction of water is most effectively probed by relaxation studies involving the NMR-active nuclei in water (^1H , ^2H , and ^{17}O , see **Table 1**). The role of water as a plasticizer of amorphous biopolymer phases has been investigated with transverse relaxation measurements involving these nuclei. 1D and 2D solid-state NMR techniques exploited spectral features of ^{13}C and ^1H nuclei to study structure and dynamics of water in, for example, crystalline and amorphous starch. Such methods have also been combined with longitudinal and transverse relaxation to obtain information on molecular dynamics. Here, ^1H NMR field cycling studies have been particularly informative, in particular for studying hydration phenomena. The interaction of water with dissolved biopolymers is typically studied by high-resolution NMR in the frequency domain. In the gelled state, cross-relaxation (or z -spectroscopy) has been used, as well as ^2H lineshape and relaxation studies on gels prepared with deuterated water.

Supramolecular and Nanostructural Order and Dynamics

High-resolution ^{13}C CPMAS solid-state NMR experiments have successfully been used to assess crystal

polymorphism in lipids, which is an important feature for explaining and understanding melting behavior of, for example, chocolate and margarines. Such solid-state NMR techniques have been deployed to study the semicrystalline order in carbohydrate biopolymers such

as starch and cellulose. Combinations of ^{13}C CPMAS and ^1H relaxometry (T_1 , $T_{1\rho}$, T_2) measurements have proven useful to study molecular dynamics in ordered biopolymers, in particular for assessment of semicrystalline order and mobile amorphous states. Thus, useful insights have

been obtained on the effects of gelatinization and retrogradation (staling) of starch-based foods. In principle, the anisotropic lineshapes produced by quadrupolar nuclei such as ^2H could have been deployed for studying order and dynamics. Such studies, however, require deuteration of the compounds of interest. This is cumbersome for most food-based systems, an exception being the introduction of deuterated water as a monitor for structure and dynamics at the nanoscale. In a complementary manner, information on the existence and nature of ordered and amorphous domains can be obtained using stable nitroxide-based radical probes that produce ESR signals that are very sensitive to ordering phenomena. Although high-resolution NMR methods provide less detailed information at the molecular level, ^1H NMR

relaxometry is still a convenient and quantitative tool for overall assessment of crystallization and ordering phenomena in foods. The measurement of solid fat content by relatively cheap benchtop NMR equipment has become a routine method for quality and process control in development and manufacturing of fat-based food products.

Microstructural Order and Dynamics

^1H NMR diffusometry and relaxometry are proven methods for rapid and quantitative assessment of microstructural parameters in foods. In most cases, the ^1H NMR relaxation and diffusion properties of water, and sometimes oil, are used to probe food microstructures.

Figure 5 Examples of dynamic MR imaging of foodstuffs: (a) proofing of dough and (b) cooking of rice. Times are indicated in minutes. Courtesy of G. van Dalen, Unilever R & D.

The enhanced transverse (T_2) and longitudinal (T_1) relaxation rates of water at pore walls can be used to assess effects of storage and processing on food microstructures. A complication is the lack of simple models that describe NMR relaxation behavior in complex and heterogeneous food materials. One typically takes recourse to multi-exponential fitting or regularization methods to extract discrete continuously distributed exponential functions from transverse or longitudinal relaxation decays. These functions are then given physical meaning by considering effects of surface relaxation, susceptibility mismatches between different microstructural components, and diffusional averaging. Alternatively, multivariate methods have been applied as a means to extract microstructural information in a less hypothesis-constrained manner. In a similar manner, one can exploit the relation between the diffusional behavior of water (or oil) with the surrounding microstructure. In recent years, two-dimensional approaches have also been used to assess relaxometric (T_1 – T_2) and diffusional behavior in a joint manner. An advantage of these approaches is that in the resulting T_1 – T_2 and T_2 – D maps one can resolve otherwise overlapping microstructural features and observe exchange between different populations. A particularly strong diffusometric application is the quantitative assessment of oil and water droplet sizes in food emulsions by exploiting the restricted self-diffusion that occurs in droplets. The aforementioned relaxometric and diffusometric applications are highly amenable for implementation on relatively low-cost benchtop NMR spectrometers, designed for use in manufacturing environments. Currently, the most prominent applications are water and oil droplet sizing in food emulsions such as margarine and mayonnaises.

Microscale/Macroscale Order and Dynamics

MRI is a noninvasive imaging technique, which visualizes the internal micro- and macrostructure of food products. **Figure 4** shows examples of MR images of several food products. The contrast in these images is based mostly on the diffusional and relaxation NMR properties of water, and can be used to understand and predict food quality. This has opened up the possibility of noninvasive quality inspection of fruits, vegetable, cheeses, fish, and meat. The ability of MRI to resolve the internal features in food materials is best exploited when microstructural events need to be assessed in a dynamic manner, such as during processing (**Figure 5**) and shelf life. Such dynamic MRI experiments are typically performed to develop and validate models for heat and mass transport in foodstuffs during, for example, drying, storage, heating, proofing, cooking, frying, and baking. In several cases, dynamic MRI has been applied to food systems under stress and shear (Rheo-MRI) to develop and validate rheological models. In all these applications, one needs to carefully select an adequate MRI experiment and tune it toward delivering meaningful and quantitative information. One can discern slow events involving relatively low molecular mobilities, and fast events and concomitantly large molecular mobilities. In the first case, one finds drying processes and moisture and oil migration during shelf-life of foodstuffs. Here, one typically takes recourse to solid-state MRI, where single-point imaging techniques have acquired a prominent position. In the second case, one finds food processes such as freezing, thawing, microwave heating, cooking, and baking. Here, one typically deploys spin–echo based methods and variants

Figure 6 Schematic overview of the interactions between diet, gut microbiota, and the human host, and sampling points of the different metabolomes.

thereof, which can provide noninvasive temperature maps of food products during freezing, thawing, and microwave heating. MRI has been particularly useful for monitoring structural events that take place during cooking of noodles and rice, proofing of dough, and the baking of bread. MRI is still a relatively expensive tool, in particular when operated on dedicated wide bore (>10 cm) scanners designed for whole-body *in vivo* applications. Hence relatively low-cost wide bore MRI scanners have been designed for dedicated applications such as quality inspections of fruits and vegetables and foreign body detection. Most research is performed on conventional high- or low-field NMR spectrometers, equipped with (micro)MRI accessories, typically suitable for relatively small sample diameters (<3 cm).

Impact of Food and Nutrition on Consumers

Biological Impact

Nutritional research investigates the impact of complex food ingredients on an even more complex biochemical system, that is, the human consumer. Until recently, nutritional research strongly focused on preidentified biomarkers. A movement is being witnessed toward more exploratory, 'omics' approaches, which assess living organisms in a holistic manner. Metabonomics is now taking a firm position within nutritional research since it can provide direct feedback on phenotype and metabolic effects of nutritional interventions. NMR-based metabonomics can assess metabolites down to the tens of micromolar level. This may seem high when compared to more targeted methods, but NMR has the unique advantage that it can assess many metabolites in a reproducible and quantitative manner in one single shot. Thus, NMR profiles of urine, blood, and even feces have been deployed to recognize human phenotypes and their response to diet (Figure 6). Thus, NMR-metabonomics has been critical in recognizing the strong interactions between diet, the gut microbiome, and the human host. In a complementary manner, MRI can provide phenotypical information on, for example, distribution of adipose and muscle tissue in humans.

Sensorial and Psychological Impact

The most immediate physical interaction between food and the consumer takes place during chewing and swallowing in the mouth. Rapid MRI techniques have been used to study processing of food in the mouth and provided insight in effects of mastication and concomitant

flavor release. MRI has also been used to visualize further processing of foods in the gastrointestinal tract. Thus, valuable information has been gathered on consistency and viscosity of foods in the stomach, and how this affects feelings of satiety. Until recently, food scientists had to rely on sensorial panels and questionnaires for gaining insight in the perception of foods by consumer. fMRI has provided a unique tool to visualize processes in the brains of consumers in an objective manner. Thus, one has been able to locate regions in the brain that are associated with perception of taste, smell, and texture, and even food preference. This has provided leads to understand emotions associated with enjoying food.

Symbols

a	pore width
$D(\Delta)$	water diffusion coefficient
f	correction factor
G	gradient amplitude
L	FID liquid signal intensity
M_0	initial magnetization
$P_{av}(R, \Delta)$	average displacement propagator
P	permeability
q	diffusion wavevector defined as $(2\pi)^{-1} \gamma G \delta$
R	distance diffused by a spin
S	amplitude of solid component in FID
S	FID solid signal intensity
$S(q, \Delta)$	stimulated echo amplitude
t_1	pulse separation time
T_2	transverse relaxation time
W	width of lamellar regions
Δ	diffusion time
γ	gyromagnetic ratio

The applications of NMR in food science have been the subject of several international conferences, reviews and books which are cited in the Further Reading section. This intense interest in the NMR spectroscopy of food is driven not only by the commercial importance of food, but also by the intellectual challenge of unravelling the physicochemical properties of this exceedingly diverse and complex group of materials. In order to focus on food aspects, it will be assumed that the reader is familiar with the principles of NMR and magnetic resonance imaging (MRI), which are lucidly explained in other articles of this encyclopedia.

Spatially Resolved NMR Applications

MRI is having a major impact on our understanding and control of the growth of food crops, on our assessment of fruit and vegetable quality and in developing the best methods of fruit and vegetable preservation. Moreover, by providing noninvasive, real-time images of moisture and lipid distributions, as well as spatial maps of temperature and food quality factors, MRI has the potential for making a major impact on food processing science.

We therefore begin with a brief review of whole-plant functional imaging, then progress on to MRI applications in food processing and storage.

Functional Imaging of Whole Plants

The growth of agricultural crops is affected by many factors, including drought (osmotic stress), luminescence, disease and soil pollutants, such as heavy metals. By permitting noninvasive monitoring of a whole plant under realistic environmental conditions, MRI has become a powerful tool in the plant physiologists' armoury. The development of small seedlings can be observed directly inside adapted NMR tubes. Larger plants can be grown in controlled-environment boxes, which bathe the root system in nutrients, and control humidity, temperature and luminescence. The root system, stem or leaf areas can then be imaged noninvasively. Root imaging is now an established technique, though it is not applicable to all soil types because paramagnetic impurities in the soil can severely shorten the water relaxation time. Nevertheless, three-dimensional (3D) T_1 -weighted imaging has been used to distinguish roots and soil in developing pine seedlings, to follow water depletion zones around the tap root, lateral roots and fine roots, and to follow the effects of symbiotic relationships, such as infection with mycorrhizal fungus, on water uptake. The increase in root network volume and surface area can also be measured from the 3D images.

A combination of flow imaging and chemical shift imaging has been used to monitor the effect of environmental stresses on the flux of nutrients through the plant stem. For example, chemical shift imaging has been used to map the spatial distribution of sucrose, glucose, glutamate, lysine, arginine and valine in castor bean seedlings. If, at the same time, the velocity distribution through the vascular bundles in the stem is observed with phase-encoding MRI, the product of the concentration and flow rate gives the nutrient fluxes. The effects of varying osmotic stress and luminescence on the nutrient fluxes can then be monitored nondestructively. Table 1 lists examples of this type of application.

Imaging Quality Factors in Intact Fruit and Vegetables

Understanding the development of the whole plant under realistic environmental conditions is only one

Table 1 Applications of functional imaging to the development of fruit and vegetables

Plant	MRI technique	Phenomenon
Castor bean seedlings	Flow imaging, chemical shift imaging	Effect of environmental stresses on nutrient fluxes
Maize and millet	Proton density mapping, T_2 mapping	Osmotic stress
Wheat grains	Water proton density, velocity and diffusion maps	Relationship between flow and grain development
Red raspberry	Gradient-echo signal intensity	Fungal infection
Strawberry	Proton density T_1, T_2	Fungal infection

aspect of food production. The quality of unprocessed, intact fruit, grains or vegetables as they are stored or transported is just as important. Here again MRI provides a useful noninvasive monitor of the effect of storage conditions on the ripening of fruit and vegetables, on the progress of detrimental changes such as disease and bruising and on the effects of preservation processes such as chilling and surface heat sterilization.

The ripening changes in tomato are of commercial importance because they are picked when they are green and transported, internationally, in boxes gassed with ethylene. Unfortunately, on arrival the tomatoes display a wide range of ripeness from green to the red-ripe fruit and require costly (and damaging) hand-sorting. If, when first picked and boxed, the degree of ripeness could be determined non-invasively by MRI, then ripening could be made more uniform and the second sorting stage rendered unnecessary. Motivated by these considerations, Saltveit and co-workers have shown that ripening in the early green stages is associated with increased water content, and hence increased MRI signal intensity, as the locular tissue 'liquefies'. Later stages of ripening are associated with increased image graininess as small air pockets develop in the pericarp tissue.

Strawberries have also been the subject of several MRI investigations. Bruising is associated with a lengthening of the apparent transverse relaxation time (T_2^*) and an increase in apparent water proton spin density, consistent with the reduction of local magnetic susceptibility inhomogeneities as a result of the filling of the intercellular gas spaces with intracellular fluid released through membrane and cell wall damage. A similar increase in T_2^* was found on infection with the fungus *Botrytis cinerea* and permitted the diseased and healthy tissue to be T_2^* -contrasted and the rate of progress of the disease quantified as the rate of increase in the volume of infected tissue. Ripening of strawberries is associated with an increase in T_2 from about 16–25 ms in the immature green fruit to 25–100 ms in the red, ripe fruit.

Table 2 Representative MRI studies of quality factors in fruit and vegetables^a

Plant	Quality factor/process	NMR parameter
Red raspberry	Ripening	Spin-echo signal intensity
Strawberry	Ripening, bruising	Spin density, T_2
Grape berries	Ripening, drying	Chemical shift
Red raspberry	Fungal infection	Gradient-echo signal intensity
Barley seeds	Ripening	Diffusion
Wheat grains	Ripening	Diffusion and flow
Tomato	Ripening	Spin density, T_1
Mango	Heat sterilization	Relaxation-weighted signal intensity
Blueberry	Freezing-thawing	T_1 discrimination of sugar and water
Cherry	Ripening	T_1 , D and volume selective spectroscopy
Papaya	Heat injury	Spin density, T_1, T_2

^aFor references see Hills (1998) in Further reading section.

The ability to discriminate diseased, bruised and unripe regions from healthy ripe tissue is essential for the development of on-line MRI quality monitoring. **Table 2** lists a number of other MRI studies on the quality of fruit and vegetables, references to which can be found in the Further Reading section.

MRI Studies of Food Processing

Many foods are processed before being packaged, distributed and consumed. The major processing operations include drying, freezing, baking and extrusion, but novel processing methods, such as high-pressure treatment, are under development and can be used either alone or in combination with more conventional processing operations. By providing spatial maps of moisture, temperature and quality factors during processing, in either the off-line or the on-line mode, MRI has the potential of revolutionizing the food processing industry. The scope for this type of study is very wide and will be illustrated by a few key operations, beginning with drying.

Drying

The output of MRI drying studies is a set of moisture profiles at known drying times. The usual strategy is then to fit the profiles with appropriate mass transport models, which are used subsequently to optimize the drying conditions for maximum product quality with minimum energy expenditure. In practice, complexities, such as shrinkage, case hardening and spatially varying diffusivities, have meant that the MRI data do not always conform to simple drying models, and this has highlighted the need for more refined theoretical models. **Table 3**

lists a number of MRI drying studies on foods such as pasta, potato and apple.

Rehydration

The quality of extruded cereal products, such as pasta, depends on extrusion temperature and the variety of wheat used in the extrusion process. The effect of varying the ratio of hard and soft wheat on the rehydration kinetics of extruded spaghetti has been investigated by MRI. By measuring the moisture profiles at various times as the spaghetti is cooked in hot water it was shown that increasing the amount of soft wheat shifts the rehydration kinetics from a case II situation, where there is a fairly sharp water front ingressing into the pasta, towards rehydration by conventional Fickian diffusion. Other MRI studies have been reported for the rehydration of starch films and air-dried apple tissue. Besides simple Fickian diffusion, the Thomas Windle model provides a useful theoretical tool for analysing the rehydration kinetics, especially near the case II regime. **Table 3** lists a number of MRI rehydration studies.

Freezing

Ice has a proton transverse relaxation time of just a few microseconds, so it does not contribute signal in conventional liquid-state MRI. Freezing is therefore associated with a progressive loss of signal and this provides a powerful tool for investigating freezing kinetics. The freezing of raw potato has been imaged at various resolutions. At low spatial resolution an ice front is observed to ingress into the food. But with smaller samples and higher spatial resolutions ($\sim 40 \mu\text{m}$) there appears to be a gradation in signal intensity throughout the sample, indicating that different regions are associated with different amounts of unfrozen water. This observation is, perhaps, a consequence of the different freezing behaviour of starch granules, cell walls, vacuolar and cytoplasmic regions in the potato cell, though the possibility of ice 'channelling' in the extracellular spaces cannot be discounted. Like drying and rehydration, finding suitable theoretical models to quantify this type of behaviour presents a considerable theoretical challenge. **Table 3** includes a number of MRI food freezing studies. The potential of using MRI as an on-line monitor of food freezing has yet to be exploited but clearly has considerable potential.

Freeze-Drying

Despite the earlier statement that ice does not contribute signal in conventional MRI, it has, nevertheless, been possible to image the shrinkage of the frozen core in potato during freeze-drying. In this example there is sufficient unfrozen water in the 'frozen' potato to permit the core to be imaged. The absence of liquid water, which would saturate the signal, is another important factor,

permitting high receiver gains during image acquisition. The time course of the sublimation of the frozen potato core was shown to follow a simplified freeze-drying model.

Temperature Mapping and Thermal Transport

Most food processing operations involve not only mass transport but also simultaneous heat transport. By providing real-time temperature maps, MRI can also be used to monitor heat transport. All that is required is an NMR parameter, such as a relaxation time, chemical shift or water diffusivity that depends uniquely on temperature over the desired range, so that, after calibration, a map of the parameter, or the parameter-weighted signal intensity, can be converted into a temperature map. **Table 4** lists a number of examples of MRI temperature mapping. The technique has been applied to the problem of aseptic food processing in which a fluid suspension of food particles is thermally processed in a continuous process. The problem here is knowing whether the central regions of the particles have attained sufficiently high temperature to ensure complete cooking and sterilization.

Imaging Quality Factors in Processed Food

Processing involves not only mass and heat transport but also changes in quality factors associated with microstructure, phase changes, gelatinization, aggregation and chemical or enzymatic reactions. Some of these changing quality factors are not amenable to NMR measurements, colour and aroma being obvious examples. However, in many cases NMR parameters are sensitive to quality factors so that MRI can be used to image changes in food quality during processing and storage. Chocolate confectionery is a typical example of this type of study. The long-term storage stability of fat-containing foods, such as chocolate, can be affected by fat crystal growth and polymorphic transitions in the solid fat phase. The MRI signal from cocoa butter arises from regions of high lipid chain mobility and so depends both on the solid-liquid ratio and, because each polymorph is associated with different chain mobility, on the polymorphic state of the solid lipid components. For this reason transverse-relaxation time-weighted MRI has been used to distinguish regions of chocolate that have melted and resolidified from those that have remained solid throughout. The migration of liquid lipid components between two phases in multilayer confectionery products greatly affects the long-term quality of the product. For example, the transport of liquid triglycerides from a praline filling into the surrounding solid chocolate layer in a filled chocolate sweet can alter thermal stability and accelerate blooming on the chocolate surface. Accordingly, MRI has been used to image the transport of liquid lipids into chocolate in a model lamellar, 2-layer chocolate product, consisting of a layer of hazelnut oil and sugar layered over with dark chocolate. The lamellar structure permitted a 100 μm spatial resolution to be achieved and the time course of the lipid migration was followed over an 84 day period for two samples stored at 19 and 28 °C. Intensity changes in the profiles were converted to liquid lipid concentrations by calibrating with homogeneous samples of known liquid-fat content. At 19 °C, the liquid lipids were observed to accumulate at the interface between the hazelnut oil and the chocolate layers. In contrast, at 28 °C, the lipid accumulated at the chocolate surface. Other examples where MRI has been used to image lipid transport and its effect on quality include the migration of fat into bread from peanut butter and the separation of cream from milk over a 9 h period.

The spatial distribution of fat in meat affects quality factors such as texture and has been imaged with chemical shift and T_1 -weighted imaging. A number of feasibility studies have shown that MRI can detect bruises in apples, pears, onions and peaches, and detect the deterioration of apples in storage, watercore distribution in apples and core breakdown in pears. The quality of cereal products is also amenable to MRI analysis. The staling of baked biscuit 'sweetrolls' over

Table 5 NMR studies of food quality factors^a

Food	Quality factor	NMR technique
Chocolate	Lipid migration	MRI

Meat	Curing/brining	^{23}Na NMR
Various fruits	Bruising	T_2^* -weighted MRI
Cookies (sweet rolls)	Retrogradation	M_0 maps

^aFor references see Hills (1998) in Further reading section.

several days' storage has been imaged and shown to be associated with a migration of moisture from the inside to the outside of the sweetroll. **Table 5** lists a number of examples where MRI has been used to image quality factors.

Flow Imaging and Food Rheology

Knowledge of the rheological properties of food pastes, slurries and sauces, such as ketchup, mayonnaise and salad creams, is important both for quality assurance and for optimizing industrial flow and mixing processes. Unfortunately, many food slurries and pastes are opaque and do not lend themselves to flow studies with conventional techniques such as laser Doppler anemometry. Moreover, conventional rheological measurements are model-dependent in that it is necessary to fit the data by assuming a functional relationship between the stress and strain (or strain rate) and to assume a set of boundary conditions (such as slip or stick) at the fluid-container interface. This is satisfactory when it is known that the fluid has a simple rheological behaviour, such as that of a Newtonian or power-law fluid. However, many liquid foods do not conform to simple rheological models so their stress-strain relationship, usually called the flow curve, must be deduced in a model-independent way. MRI can do this by imaging the velocity profile at every point in a rheometer, including the boundary layer (at least within one voxel dimension). The rheometer can be of any of the standard types, including a cylindrical tube and rotational viscometers (or couette cell). **Table 6** lists a number of representative MRI rheological studies.

Shear-Induced Nonrheological Changes

Shear-induced aggregation in concentrated food emulsions such as dairy creams and shear-induced particle migration are just two examples of microstructural or compositional changes caused by shear. These changes can be studied with MRI methods by combining flow

Table 6 Flow imaging studies of food-related materials^a

Fluid	Apparatus	Phenomenon
Nutrient fluid	Hollow fibre bio-reactor	Starling flow
1.5% Carboxymethyl cellulose solution	Tube flow	Rheology
Tomato juice	Tube flow	Rheology
Fibrous suspensions	Tube flow	Rheology
Carboxymethyl cellulose solution	Extruder	Velocity field in an extruder
Particle suspensions	Tube/couette flow	Shear-induced migration
Xanthan gum	Tube flow	Shear thinning and apparent wall slip
Egg-white, cornflour/water, tomato sauce	Couette, flow/cone and plate flow	Shear-induced phase transitions

^aFor references see Hills (1998) in Further Reading section.

imaging with MRI spatial maps of NMR parameters, such as relaxation times or spin densities, which are sensitive to the microstructural changes. Table 6 includes a number of examples of this approach.

Flow and Quality Assurance

On-line quality control of food slurries and pastes often requires rapid, empirical, rheological tests based on flow times or flow lengths rather than quantitative measurements of well-defined rheological parameters such as shear viscosities. The Bostwick consistometer (which is used to determine the quality of puréed fruit and vegetable products), the Brabender Visco-amylograph (which is used to test the consistency of starches) and the Torque plasticorder (used for dough consistency) are examples of such empirical rheological testing. MRI studies of the flow within these various test rigs, such as the Bostwick consistometer, have helped provide a rheological rationale for these empirical measurements.

Flow in Extruders

Pioneering MRI studies on flow in an extruder have been reported by McCarthy and co-workers (see Further Reading section) who designed a special nonmagnetic single-screw extruder for operation inside the magnet of an NMR spectrometer, and used carboxymethyl cellulose solution as a model extrudate. The flow patterns were compared with theoretical models of extruder flow for an incompressible Newtonian fluid. This type of study has considerable research potential because extrusion is used widely throughout the food industry for the manufacture of pasta, snacks, confectionery, pet foods and animal feeds. Despite this, extrusion is, perhaps, the least understood of all food processing operations, involving

complex series of physical and chemical changes such as mixing, gelatinization, denaturation, evaporation, flavour production (and loss) and rheological changes. To date only the flow aspects of extrusion have been studied by MRI, but, by exploiting relaxation and diffusion weighted imaging techniques, the potential exists for exploring other associated physical and chemical changes.

NMR Diffusion Studies of Food Microstructure

The use of pulsed gradients and fringe field gradients in NMR diffusion measurements has been widely documented in the research literature and is reviewed in other articles of this encyclopedia. Provided certain conditions are fulfilled, such as factorization of the effects of relaxation and diffusion and translational invariance, the pulsed-gradient techniques permit measurement of the average displacement propagator, $P_{av}(R, \Delta)$, where R is the distance diffused by a spin in the diffusion time, Δ . Various theoretical models have been developed relating $P_{av}(R, \Delta)$ to microstructure in simple geometries, so that measurements of the average propagator can be used to gain information about food microstructure. In favourable circumstances, microstructural information on the submicrometre distance scale can be accessed by this approach, which greatly exceeds the spatial resolution in NMR microscopy. In the following we consider the application of diffusometry to various food systems, including gels, cellular tissue and emulsions.

Diffusion Studies of Gels and Starch-Based Systems

The microstructure of starch and gellan gum gels has been investigated by the stimulated-echo pulsed-gradient method as a function of increasing diffusion times, Δ (up to 1010 ms), and at various gradient amplitudes, G , at fixed gradient pulse duration δ and pulse separation, t_1 . An effective water diffusion coefficient, $D(\Delta)$, was extracted by assuming the echo attenuation for unrestricted diffusion,

$$\ln[S(q, \Delta)/S(q = 0)] = -D(\Delta)(4\pi q)^2(\Delta - \delta/3)$$

The gel microstructure caused the coefficient $D(\Delta)$ to decrease with increasing Δ , and this decrease was fitted with the model of von Meerwall and Ferguson. This model represents the gel micropores as a series of parallel compartments of width, a , separated by barriers of permeability, P . Within each compartment the intrinsic water diffusivity was assigned the value, D_0 . Pore sizes, a , of the order of 10–15 μm for starch gels and 5–15 μm for gellan gums were deduced and these varied slightly with gel concentration, and, for gellan gums, with ionic strength. These pore spacings appear to be rather large for these

concentrated gel systems and, in the case of starch gels, may reflect the presence of residual granule structure resulting from incomplete gelatinization. The effects of retrogradation on starch gel microstructure were also followed in these studies, and were associated with changes in pore size and water diffusivity. Fringe field diffusion methods have been used to monitor water diffusion in gelatine gels of increasing concentration and in protein aerogels obtained by freeze-drying. The diffusion behaviour in the aerogel system was shown to be anomalous, and akin to diffusion in a fractal space. Echo attenuation of the pulsed-gradient stimulated echo of water in packed beds of potato starch granules appears to conform to diffusion in a lower dimensional space, lying between one and two dimensions, depending on the water content. This could be a consequence of the crystalline A- and B-type starch regions in the granule, channelling the water translational motion, but further work is needed to test this hypothesis.

Diffusion Studies of Cellular Plant Tissue

The pulsed-gradient stimulated-echo sequence has been used to investigate the effects of electrical and conventional heating on intercell permeabilities in carrot tissue. The echo attenuation was interpreted with a lamellar cell model in which carrot cells were represented as lamellar regions of width, W , containing water of diffusivity, D , and separated by a barrier of effective permeability, P . Presumably this barrier arises from the combined effect of diffusion through the tonoplast, cytoplasm, plasmalemma and cell wall subcellular compartments. It was found that cooking increases the apparent diffusion coefficient and barrier permeability, which is consistent with the breakdown of cell structure, but there were also small, but statistically significant, differences between electrical and conventional cooking.

Diffusion Studies of Food Emulsions

The determination of droplet-size distributions in water-in-oil or oil-in-water emulsions by pulsed-gradient diffusion measurements is now a routine industrial method for monitoring the quality of food emulsions such as mayonnaise and salad creams. The method was first described in a classic paper by Packer and Rees (see Further Reading section) and subsequently developed into a rapid analytical method. The theoretical model assumes spherical droplets and a log-normal size distribution, but other distributions have been considered. The MRI generalization of the method to spatially dependent droplet-size distributions in emulsions undergoing coalescence and/or phase separation has yet to be implemented, although a spatially dependent study of emulsion crystallization has been reported.

Cheese is, in essence, a distribution of fat droplets in a protein–water matrix. The fat droplet size distribution has been studied by the NMR diffusion method and showed a very broad Gaussian size distribution with significant differences between Swiss and Cheddar cheeses. In this sample the water signal could be removed by using a long echo time, because the water transverse relaxation time was much shorter than that of the fat. The water diffusion was also shown to be consistent with 1D diffusion along the protein chains in the cross-linked protein matrix of the cheese. In this case the water signal was separated by Fourier transforming the echo obtained at shorter echo times. This resulted in separate peaks for the fat and water.

NMR Relaxation Studies of Food

Relaxation Studies of Food Microstructure

NMR relaxation time measurements provide a unique window to view both food microstructure and the dynamic behaviour of molecules comprising the food matrix. The microstructural aspect arises because different aqueous microscopic compartments are usually associated with different intrinsic water-proton relaxation times. Provided the exchange of water magnetization between compartments is slow on the NMR measurement timescale, the distribution of water-proton relaxation times therefore reflects the number and relative volumes of the microscopic compartments. The proviso that the exchange is slow is important, because if the exchange is fast, then only a single average relaxation time will be observed and all compartmental information is lost. Like diffusion, theoretical models are required to relate the observed relaxation-time distribution to microstructure, and these models are usually based on numerical solution of the Bloch–Torrey equations. The Monte Carlo method is perhaps one of the most powerful solution tools for doing this. A cube is divided into N^3 volume elements and the morphology of the system is defined by assigning compartments (or regions) within the cube characterized by intrinsic relaxation times and diffusion coefficients. Magnetization density vectors are then randomly distributed throughout the cube, which then diffuse between voxels and relax with a rate corresponding to their location. In this way echo-decay amplitudes for the CPMG (Carr–Purcell pulse sequence, Meiboom–Gill modification) and pulsed-gradient diffusion sequences can be calculated and analysed with one of the standard deconvolution software packages.

Numerical solutions of the Bloch–Torrey equations have been used to interpret relaxation data for a variety of microscopically heterogeneous model systems, including randomly packed, water-saturated beds of Sephadex, silica and glass microspheres. Their application to plant cell tissue is perhaps more directly relevant to food. The three

major compartments in a plant cell are the vacuole, cytoplasm and cell-wall region, though starch granules comprise an additional compartment in some foods, such as potato. The Bloch–Torrey equations describing relaxation and diffusive exchange between these intracellular compartments have been solved for an idealized three-compartment spherical cell morphology and used to predict the dependence of the relaxation-time distribution and pulsed gradient spin-echo (PGSE) diffusion behaviour of apple tissue, both fresh and during air drying. The latter showed that water is removed mainly from the vacuolar compartment during air-drying, and that this is associated with volume shrinkage of the tissue. The sub-cellular changes induced by the freezing and drying of potato and carrot have also been investigated in this way.

Relaxation Studies of Aqueous Solutions, Gels and Glasses

There are at least two proton pools in aqueous solutions of dissolved sugars, proteins and polysaccharides, namely the nonexchanging CH proton pool and the exchangeable pool of protons on water and biopolymer/solute hydroxyl and amino groups. Fast proton exchange between the water and exchangeable biopolymer protons means that any process, such as denaturation or gelation, that changes the rigidity of the biopolymer chains will result in an altered transverse relaxation time of both the exchangeable ‘water’ and the nonexchanging proton pools. The latter can be observed by replacing water with D₂O, or, at sufficiently high concentrations, as a faster relaxing component in the free induction decay (FID). The transverse relaxation rate of the exchangeable ‘water’ proton pool can be monitored as a slowly relaxing component in the FID or, more usually, with the CPMG pulse sequence, and can be used to follow the kinetics of gelation and denaturation. This approach has been used to follow the thermal denaturation of whey proteins and the gelation of pectins and starch.

Longitudinal and rotating-frame relaxation in these systems is complicated not only by proton exchange but also by the possibility of secular dipolar cross relaxation between all proton pools. This makes theoretical modelling difficult, although it does not prevent longitudinal relaxation being used empirically to monitor food processing changes.

At lower water contents, below ~50% by weight water, the signal from the nonexchanging solute proton pool appears clearly as a faster relaxing component in the FID and can be characterized with an effective T_2 by analysing the decay as either Gaussian or exponential. For example, in concentrated gelatine gels, the fast relaxing component has a T_2 of the order of a few tens of microseconds, and this increases with increasing water content as the gelatine chains are plasticized. Plasticization, which permits high-

energy ‘strained’ interchain conformations to be relaxed, can result in increased local order and changes in texture. For this reason it has been investigated in a number of cereal proteins that are important in controlling the functional behaviour of dough and bread, such as glutenin in wheat and chordein in barley. Retrogradation in starch-based foods is one of the most important examples of plasticization, and permits the partial recrystallization of amylopectin chains into A or B crystallites, and results in the staling of bread and cake products. The retrogradation kinetics can be followed from the concomitant decrease in the water-proton relaxation time, and the lowering of the glass transition temperature by plasticization can be modelled with the polymer science approach.

NMR and Food Compositional Analysis

High-Resolution NMR Spectral Studies

The application of high-resolution NMR methods to molecular structure elucidation of purified proteins, polysaccharides and lipids is too extensive to be treated in depth in this chapter. The use of ¹H high-resolution solution-state NMR spectroscopy, in combination with enzymatic debranching and chromatographic purification, for elucidating the molecular structure of complex food polysaccharides, such as amylopectins, carrageenans, pectins and alginates, has been reviewed (see Gil and co-workers in the Further Reading section). High-resolution liquid-state ¹H and ¹³C NMR has also been widely used in the compositional analysis of lipids in vegetable and fish oils and **Table 7** indicates the extent of this type of study. Cross-polarization magic angle spinning (CP MAS) spectroscopy and other high-resolution solid-state NMR methods have been used to study structure–function relationships in the solid and gelled states of starches and other polysaccharides. Multinuclear NMR spectroscopy has been especially valuable for understanding cation–polysaccharide interactions in ionic food polysaccharides, and some examples are listed in **Table 8**.

The low-speed MAS technique is worthy of special mention because it overcomes spectral-line broadening artefacts from local field gradients created by differences in magnetic susceptibility across phase boundaries in microscopically compartmentalized foods. This technique has been used to obtain well-resolved spectra of sugars and metabolites in intact fruits, and to resolve water and oil peaks in multiple water-in-oil-in-water emulsions, found, for example, in low fat spreads. The detection of food adulteration is of increasing commercial importance and several high-resolution NMR methods, such as site-specific natural isotope fractionation (SNIF) NMR, are being used routinely for food authentication, and have been extensively reviewed (see the Further Reading section).

Table 7 Some NMR studies of food lipids^a

<i>Lipid</i>	<i>Nucleus</i>	<i>Analytical purpose</i>
Vegetable epoxidized oils	¹³ C	Epoxy acid content

Low-Resolution NMR Analysis of Food Lipids

The NMR analysis of the oil content of seeds relies on the differences in proton transverse relaxation times of the constituents. Typical T_2 values of solid macromolecules in seeds are just a few microseconds, and so they appear as the initial, rapidly decaying part of the FID. Water in seeds is strongly adsorbed to macromolecules and so has a short T_2 (of the order of a few milliseconds). In contrast, oil exists as liquid droplets in the seeds and therefore has a relatively long T_2 (of the order of hundreds of milliseconds). This means that the oil content can be determined directly from the FID as the ratio,

$$\text{Seed oil content (\%, w/w)} = 100L(L + fS)$$

where L is the FID signal intensity measured after the solid signal has decayed and near the beginning of the liquid signal (typically after $\sim 75 \mu\text{s}$) and S is the FID intensity of the slightly decayed solid signal. The correction factor, f , takes account of the decay during the instrument deadtime (typically the first 5–10 μs). The Hahn-echo pulse sequence is an alternative means of determining oil content. The water signal can be eliminated by choosing an echo time much longer than $5T_2$ of the seed water, the remaining oil signal then being calibrated with standard oil samples.

Alternatively, the echo amplitudes of the full CPMG echo-decay envelope acquired at short interpulse spacing can be analysed as a multiple exponential decay, whose relative weightings are proportional to the water and oil content of the seed. If this measurement is combined with the relative solid to liquid ratio determined from the FID, the complete solid–oil–moisture content of the seeds can be determined. Solid to liquid fat ratios in chocolate can be determined in a similar way. **Table 7** includes a number of such low-resolution studies of food lipids.

The exquisite analytical sensitivity and specificity of MS have found numerous and diverse applications in the field of food science.

Trace analysis for undesirable chemical contaminants in foodstuffs is conducted in many laboratories around the world. This may be for quality control, regulatory or surveillance purposes. MS is frequently the analytical method of choice because of its ability to produce unequivocal data.

Organic compounds sought include naturally derived materials, such as mycotoxins and off-flavours (produced by rancidification or spoilage), and man-made/industrial chemicals, e.g. pesticides, veterinary drugs, environmental contaminants (such as polychlorodibenzo-*p*-dioxins, polychlorinated biphenyls, polynuclear aromatic hydrocarbons, etc.) and food tainting compounds (e.g. 2,4,6-trichloroanisole, the compound responsible for musty cork taint in wine, arising from the inappropriate use of wood preservatives). GC-MS and HPLC-API-MS are widely used for these types of analyses. Desirable food components present at trace levels, such as nutrients, are also determined using these techniques.

Trace levels of inorganic chemical species, e.g. lead, arsenic, cadmium, are also monitored in foodstuffs, often using ICP-MS. The advantage of MS over AAS is that several elements may be measured simultaneously and the concentrations of individual isotopes may be measured, facilitating metabolism/nutrient studies with stable isotope materials. Precise determination of isotope ratios (e.g. C, N and O) by IRMS is also important in agricultural and food authenticity studies. Accelerator mass spectrometry is used in tracer studies, for the determination of extremely low levels of carbon-14 (and other) isotopes.

Table 1 summarizes the ranges of analytical sensitivities required for different classes of food analysis.

Table 1 Typical analytical sensitivities required for various classes of food contaminant/component

Class	Typical concentraion sought (by weight)
Flavours	% - ppb
Food taints	% - ppq
Pesticide residues	ppm - ppb
Trace elements	ppm - ppb
Mycotoxins	ppb
Dioxins	ppt - ppq

Much work has been done on the characterization of food flavours and aromas by GC-MS. A significant recent advance has been the use of APCI and drift tube MS techniques for sensitive, on-line ('real time') monitoring of trace volatiles, e.g. in human breath during flavour release studies.

Characterization of unfractionated foodstuffs and related materials for screening or taxonomic purposes may be performed by pyrolysis MS and direct headspace MS. These techniques generate rather simple mass spectra that may be classified using pattern recognition/chemometric software.

MS is also used for the analysis of the more abundant (non-trace) components of food, e.g. oils and fats (triglycerides), proteins and carbohydrates. Analysis of these materials is often challenging, as they may comprise complex mixtures of isomeric compounds. Modern MS techniques (MALDI TOF and electrospray ionization) have become extremely important in protein and peptide studies.

Forensic Science, Applications of IR Spectroscopy

Núria Ferrer, Universitat of Barcelona, Spain

This article is reproduced from the previous edition, volume 1, pp 603–615, © 1999, Elsevier Ltd., with revisions made by the Editor.

Introduction

For many years, infrared (IR) spectroscopy has been one of the main techniques used for molecular identification. Conventional dispersive infrared spectrometers have been replaced by Fourier-transform infrared equipment, which incorporates a Michelson interferometer and presents a series of advantages over dispersive systems, such as an improvement of energy and the simultaneous measurement of the whole spectral range.

Owing to these improvements, infrared spectroscopy underwent a marked development because of the possibility of adapting new accessories to the spectrometers and, therefore, of analysing samples whose infrared spectrum was impossible to obtain some years ago. Among these accessories are those which can measure specular and diffuse reflection, attenuated total reflectance and microscopes. One area in which the technique has improved dramatically is forensic analysis.

Many laboratories perform forensic analysis nowadays. Some of them seek to determine what is wrong with a process, while others are trying to copy a process from a competitor. The possibility of analysing and identifying microscopic particles, the accurate comparison of samples from different origins and the fact that the sample is not destroyed have also converted the FT-IR technique into a valuable tool where criminal and social implications are present. Some of the forensic materials that can be identified by infrared spectroscopy are: paints, fibres, textiles, polymers, explosives, varnishes, adhesives, papers, gemstones, drugs, food additives, fur or textile treatments and physiological samples. An important feature is the possibility of analysing solid, liquid or gaseous samples. In criminal investigations it is important to attach the infrared spectrum to each sample, since the IR spectrum is unique to every substance, like a fingerprint. In addition, in lawsuits where several parties are involved, infrared spectroscopy can contribute relevant information.

This article shows a number of applications of infrared spectroscopy to the forensic analysis of a range of samples using different accessories and methods. A number of examples are given, although applications are unlimited and any analysis might be of value in forensic research.

Main Accessories and Methods Used in Forensic Analysis

The two main restrictions of analysis by infrared spectroscopy are sample size and difficulties regarding handling. Three kinds of sample compartments are available depending on the size of the sample to be placed in the spectrometer:

- macro compartment: this employs a beam between 2 to 10 mm and any type of accessory might be fitted.
- semimicro compartment: this requires the use of a beam condenser and the spot of the beam in the sample is about 1 or 2 mm.
- micro compartment: the size of the beam is less than 1 mm and a microscope needs to be used.

A beam condenser can be installed in the sample compartment of the conventional equipment, but the microscope needs the infrared beam to go out of the bench to an externally attached accessory. The microscope uses the source and beamsplitter of the infrared equipment to which it is coupled, but it has its own more sensitive detector. Obviously, large samples can also be located on the microscope, but in such cases the measurement area is reduced to less than 100 μm . Therefore, if an analysis of the predominant material in the sample is required, its homogeneity must be assured and defects or pollutants must be avoided.

Depending on the manipulation that the sample requires, a range of accessories might be used. Many samples for forensic analysis must not be destroyed or manipulated either because they need to be kept for further analysis or because of their economic or historic value. KBr pellet measurement requires mixing the sample with the salt and, therefore, the possibility exists that it might be lost. Other methods such as diamond cell or reflection do not require any alteration or mixing of the sample with other substances. In the main, liquid and gaseous samples suffer no risk of destruction and it is only necessary to fit them in cells which are transparent in the desired range of measurement and which are also compatible with the material to be analysed. Solid samples can be mixed with salts in order to make an infrared transparent pellet, or can be placed on a suitable surface for further analysis.

Diamond Cell

A diamond cell is one of the most frequently used pieces of apparatus in forensic analysis. It is normally used when samples are very small, but can be separated from the matrix. The particle or fibre, which can be as small as 5 μm , is placed on a diamond window and put under pressure with the help of another diamond window. The pressure of the cell allows the sample to spread over the diamond increasing its surface area while decreasing in thickness. In this way, the infrared radiation is able to go through the sample and, therefore, its infrared spectrum can be obtained by transmission.

Diamond cells are about 4 mm² in aperture and depending on the area of the spot of the spread sample it is possible to utilize a beam condenser or a microscope. Despite the absorption of diamond in the mid infrared, the wavenumber reproducibility that FT-IR is able to achieve makes it possible to subtract the diamond spectrum and to obtain clean spectra of the sample. In forensic analysis this technique is applied to paints, varnishes, inks, fibres, crystals and particles in general, which can be put under pressure and suffer a deformation. To avoid excess of absorption, one of the cells can be removed. In the case of samples such as cork, tobacco and some polymers, which recover their original size after decompression of the cell, the alternative is to use two diamond windows with the sample in between, instead of removing one of them.

Specular Reflection

When a sample cannot be manipulated at all, is opaque and has a specular or polished surface, specular reflection is the technique to be applied in either the microscope or the macro compartment.

Diffuse Reflection

When the surface of the sample is not specular and there is a certain diffuse component of reflected light, or when analysing a cut gemstone, the analysis is appropriately conducted by using the diffuse reflection technique where all the light emitted by the sample is measured.

Attenuated Total Reflectance (ATR)

Attenuated total reflectance is applied to samples where the composition of the surface needs to be measured. It is applied to soft samples such as paper, fur, polymers and textiles, which can achieve good contact with the crystal used. It is also used for aqueous samples and viscous or sticky samples such as pastes, soaps and detergents. The only consideration to be borne in mind is the need to obtain good optical contact between the surface of the

sample and the crystal of the accessory, which can be made of diamond, ZnSe, Ge, Si, KRS-5 (a 40:60 mixture of thallium bromide and iodide), etc.

When the surfaces to be analysed are very small it is possible to use the attenuated total reflectance objective of the microscope. A unique internal reflection over the sample in touch with the crystal is enough to obtain the spectrum. This is the alternative when even a single particle cannot be removed from the matrix, which is the case for very ancient or valuable samples such as manuscripts, books or paintings.

Separation Techniques

Determination of complex mixtures is one of the most common problems in infrared analysis. Hyphenated techniques such as chromatography provide a useful way of separating mixtures into individual compounds. Gas chromatography (GC) has been by far the best application of combining infrared spectroscopy and a separation technique. One of the principal reasons has been the use of carrier gases which do not absorb in the infrared region.

Specific Analyses

Analysis of Paints

Infrared spectroscopy has been widely applied in the forensic analysis of paints. It is particularly useful in car accidents where it is necessary to determine the origin of the paint adhering to a car. In some countries there are car paint libraries, and it is possible to find the model of the car and the year of manufacture by analysing the paint. In the absence of witnesses, or if a vehicle has left the scene of an accident, this analysis can be a crucial element in obtaining a verdict.

Another major application of the technique is in the analysis of ancient paints used in a particular period of history or a particular place. This is essential not only for the study of the pigments and materials used by different civilisations, but also for authenticating works of art, restoration work and in lawsuits involving damaged works of art.

Figure 1 shows two spectra from two sections of a modern painting. The damage to the picture might have been caused by a heterogeneous application of oil or the poor conservation of the picture. A non-homogeneous distribution of oil over the surface was made evident when two sections of the picture were analysed. As it was possible to use part of the picture from under the frame, the amount of sample was sufficient to allow use of the attenuated total reflectance horizontal accessory.

A further application of this technique is in seeking to obtain high quality paints. Changes in pigment

Figure 1 Spectra of two pieces of a painting: the damaged painting does not show the bands corresponding to oil (ATR horizontal).

composition as well as in solvent composition can have a considerable impact in industry. Therefore, it is important to be able to determine quickly the composition of both solid and volatile fractions. In addition, increasingly stringent controls make it necessary to check for the presence of forbidden solvents in commercial paints.

Figure 2 shows the spectrum of the volatile fraction of a commercial paint. The spectrum was obtained by placing a long strip of aluminium foil on the bottom of the gas cell with some paint on the foil. After a few minutes the number of molecules within the cell corresponding to the volatile fraction is sufficiently great to obtain the spectrum of the gas. In this particular case it was possible to identify xylol as a component of the gaseous fraction. Pigment analysis can be performed by covering a KBr pellet with a very thin layer of paint.

When paint samples are very small, for example in the case of a valuable painting, or an archaeological sample or the paint which remains attached to a lead bullet once it has passed through the bodywork of a car, the most widely used technique is to put small particles on a diamond cell and to obtain the infrared spectrum by transmission. If the sample cannot be removed from the matrix, microscopy with an attenuated total reflectance objective can be used.

Fibre Analysis

Forensic analysis of fibres constitutes another major application of infrared spectroscopy. The spherical structure of fibres makes it necessary to flatten the sample before measuring its spectrum, for which it is possible to use either a roller or a diamond cell. Once the fibre is prepared, the variable apertures of the microscope allow the masks to be adapted to the size of the fibre.

Figure 3 shows the spectrum of a fibre found in a pharmaceutical product. Here, it was necessary to know whether the sample came from the filters in the industrial process or from the white coats of the workers. Although it was clear that the three fibres analysed were polyester, the technique was able to identify the kind of polyester and to determine its relation to fibres coming from the filters of the industrial process. In this case the sample consisted of a single fibre and, therefore, the use of a microscope was the only option. If the sample consists of a piece of textile or several fibres, other methods such as attenuated total reflectance, KBr pelleting following shattering after treatment in liquid nitrogen, or a diamond cell in the beam condenser can be used.

Other applications have been reported, in the field of medicine where suture threads have had harmful

Figure 2 Spectrum of a volatile fraction (xylol) of an industrial painting (gas cell).

Figure 3 Comparison of fibres from a polluted sample, white coats and an industrial filter (diamond cell in the microscope).

reactions in patients, and for analysing single fibres recovered from the scenes of crime.

The appearance of surface defects in animal furs is another reported application of attenuated total reflectance techniques. **Figure 4** shows an example of a valuable fur damaged by white spots. The manufacturer claimed that the client was responsible for damage to the fur because it had been stored in an inappropriate environment or because of treatments it had been exposed to. The client, on the other hand, claimed its original treatment during manufacture was to blame. Infrared analysis demonstrated that the white spots came from the migration of animal fat to the surface and bands were comparable to the fat extracted from the natural fur. Other substances, such as silicone, have been found in this kind of sample.

Paper and Ink Analysis

Application of the infrared technique with a microscope to inks in paper has been a useful tool. Examples include comparison of inks used on the same cheque, for example an additional zero to the total sum or in the signature, and documents which are signed and dated, where it is possible to analyse the inks from printers or hand typewriters to determine if they actually existed when the document was signed. Particles of toner from a

photocopy can also help to solve cases by comparing the particles of the document with the toner from the photocopying machine used.

Figure 5 shows the spectra obtained by transmission microscopy of two cotton fibres, one of which contains a blue ink spot. Comparison of the spectral differences between the clean fibre and that spotted with ink shows that this difference can indeed be imputed to the ink.

Cellulose fibres also have a highly characteristic infrared spectrum. Acidity of paper due to the presence of acidic inks or biological degradation can be measured by analysing the infrared spectrum. **Figure 6** shows the spectral differences in certain ranges of the spectrum due to corrosion related to the acidity of ancient papers. Carbonate bands at 875 and 1797 cm^{-1} decrease with decreasing pH, carbonyl group peaks increase with decreasing pH and hydroxyl peaks from cellulose decrease with increasing pH. This kind of change arises as a result of poor conservation or the type of paper.

Spots on papers can also be measured. **Figure 7** shows the spectra of two samples from the same piece of paper, one of which is spotted. The attenuated total reflectance objective of the microscope allows us to identify the presence of paraffins. In such cases, a microscope is essential to obtain the infrared spectrum while the attenuated total reflectance objective allows the analysis to be carried out without destroying the document.

Figure 4 Comparison of spectra of clean and dirty furs, with a spectrum of glycerine (ATR horizontal).

Figure 6 Changes of four different regions of the infrared spectrum of paper with pH (diffuse reflection accessory).

Figure 7 Spectrum of a spot on the surface of a paper identified as paraffin (ATR microscope).

Analysis of Gemstones

There is an increasing number of gemstones, treated or synthetic, that need analysing and the technique that allows them to be distinguished visually is not particularly reliable. Infrared spectroscopy can provide objective evidence for the characterization of such samples and this is very important for both identification and certification purposes in commercial and legal practices.

Diamonds are one of the more interesting groups of gems to study. Only when diamonds present two parallel faces is it possible to use transmission to determine the infrared spectrum. Normally diamonds, especially those destined for jewellery, have a brilliant cut. This cut affects the light and makes it go out in all directions. In this case the only technique that allows the measurement of the infrared spectrum is diffuse reflection. Here the gem is placed horizontally over an aluminium mirror.

Natural diamond without impurities has a characteristic spectrum with bands that are common to both natural and synthetic diamonds, but most diamonds also present bands caused by defects in the crystalline lattice. Three different ranges in the infrared spectrum can be distinguished. The first corresponds to the interval between 5000 and 2700 cm^{-1} and is the range where the bands corresponding to hydrogen impurities appear

(4499 , 4169 , 3237 , 3107 and 2785 cm^{-1}) and is characteristic of the natural diamond. The second range corresponds to the common bands of the diamond structure but they do not reveal the difference between natural and synthetic diamond (2505 , 2443 , 2159 , 2033 and 1970 cm^{-1}). Finally, the range between 1400 and 1000 cm^{-1} identifies the impurities due to nitrogen as a specific defect in the crystalline lattice. According to the type of nitrogen substitution, there are different kinds of diamonds and it is in this range that it is possible to distinguish between the natural and the synthetic stones. **Figure 8** shows the spectra of a natural diamond with hydrogen and nitrogen impurities, and of a synthetic diamond.

The spectral differences of each diamond are in general great enough to distinguish between them. It is of particular value in identifying a gem with a high commercial value. If an infrared spectrum is attached to a gem, it can be used as proof in case of legal certification. The ratio of the hydrogen or nitrogen bands to the common bands of the second region of the diamond provides a value that is probably unique to the stone.

Another group of gems for which it has been possible to measure the differences between natural and synthetic specimens is emeralds. The water and carbon dioxide content in natural gems means they can be distinguished

Figure 8 Comparison of a natural and a synthetic diamond (diffuse reflection).

Figure 9 Comparison of a natural and a synthetic emerald (diffuse reflection).

Figure 10 Comparison of bands of water in the near infrared between a natural and a synthetic emerald using polarized light (reflection microscope).

by measuring both mid and near infrared bands. **Figure 9** shows the infrared spectra of a natural and a fused phase synthetic emerald, where carbon dioxide and water are not present. Nowadays, techniques of manufacture of synthetic emeralds allow water to be incorporated in the lattice. In spite of this, infrared spectroscopy can distinguish between both kinds of water with the help of polarized radiation. **Figure 10** shows the near infrared spectra of a natural and a synthetic emerald using polarized light at 0° and 90° . In general, infrared spectroscopy enables not only the observation of the differences between certain synthetic and natural specimens, but also to obtain the fingerprint of each gem with its impurities and, therefore, to use it in judicial and commercial certification.

Polymer Analysis

Polymers are a group of substances that can easily be investigated by infrared spectroscopy. Apart from analyses aimed at identifying small particles or the composition of packagings used for food or drinks, the use of infrared spectroscopy allows multilayer polymers and adhesives used with them to be determined. **Figure 11** shows the infrared spectra of a $50\text{ }\mu\text{m}$ thick packaging where the content was altered because of migration of components from the adhesive between the layers.

The use of phthalates as plasticizers in the polymers of food packagings can lead to the migration of these molecules to the food itself. Therefore, it is essential to check for their presence in such packagings. **Figure 12** shows the attenuated total reflectance spectra of a polymer in contact with drinking water where phthalates were detected.

Analysis of Physiological Samples

Infrared spectroscopy has also been applied to the identification of particles found in organs such as the lung, kidney or liver. Some studies have been reported in which this technique has been applied to the analysis of malignant cells, by measuring the region of phosphodiester of lymphocytes. This technique has been applied to the determination of samples of normal and malignant cervical cells. The presence of biomaterials such as polyesters, polyurethanes and silicones originating from implants can also be measured.

In the field of drugs, the analysis of human and animal hairs has been reported. Application of infrared microscopy in determining the presence of drugs in inner cuts of hair samples is a useful method for avoiding false positives from external contamination.

Some minerals, including carbonates and phosphates, from both inner and external parts of bones, have also been measured.

Figure 11 Spectra of the polymer and the adhesive of a multilayer film (transmission microscope).

Figure 12 Spectrum of a PVC polymer used in contact with drinking water, showing phthalate bands at 1719 cm^{-1} (ATR horizontal).

Food Analysis

A number of analyses show the possibility of measuring additives used as preservatives in foods. Adulteration of juices, vegetable oils and milk, as well as caffeine content, protein and lipid content or sugar composition are other examples that have been reported.

Figure 13 GC-IR spectra of six aldohexoses.

Figure 13 shows the GC-IR spectra of six aldohexoses. None of the monosaccharides showed identical spectral patterns, so the technique was effective for their identification following separation by GC.

Figure 14 shows the spectrum of particles removed from the surface of frozen fish. The particles were identified as pyrophosphate.

Environmental Samples

Analysis of solid samples which might contain particles from a contamination is another area for which infrared spectroscopy might be needed. In cases where it is necessary to prove that a particular waste has been introduced in a certain place, the technique allows the nature of the particles found to be analysed. Compensation is

Figure 14 Spectrum of particles on the surface of a frozen fish, identified as pyrophosphate (diamond cell in beam condenser).

Figure 15 Spectrum of pyrite from a waste spill in the Doñana National park, Spain, showing a pyrite band at 422 cm^{-1} (KBr pellet).

often available for those who have lost crops or cattle, but evidence of pollution must be proved.

Analysis of vapours from polluted soils or from stacks can also be carried out.

Figure 15 shows the spectrum of particles from a spill near the natural park of Doñana (Spain) which caused an ecological catastrophe in 1998. The pool from which the spill originated was full of pyrite waste and a black wave covered crops over an area extending many kilometres. The band at 422 cm^{-1} corresponds to pyrite (FeS_2). Infrared spectroscopy was able to identify this compound at a distance of many kilometres from the spill.

The identification of compounds that should not occur in a place makes it possible to impute them to spills or pollution from other places.

Conclusions

To sum up, infrared spectroscopy allows a rapid, initial determination of a substance sent for forensic analysis and can provide evidence that is of great, perhaps decisive, use.

It is often difficult to identify a substance by its infrared spectrum, especially one containing organic molecules, when there is no indication of what it might be. Inorganic molecules are easier to identify, at least those bands corresponding to the anionic part of the molecules: carbonates, silicates, nitrates, sulfates, phosphates, etc. Yet, frequently it is only necessary to compare samples or to follow up a suspicion of the presence of a substance.

Libraries play an important role in forensic analysis, but the best libraries are the ones built up by analysts themselves using suitable accessories and developing their own methods.

This article is reproduced from the previous edition, volume 1, pp 615–621, © 1999, Elsevier Ltd.

An important component of forensic toxicology is the determination of drugs in biological specimens when the analytical results have potential legal consequences. Mass spectrometry is generally the primary analytical tool for these investigations. This is because mass spectrometry, in combination with chromatographic methods of sample introduction, offers the best combination of high sensitivity and reliable identification. The areas of forensic toxicology where mass spectrometry has played a particularly important role include workplace drug testing, testing of motor vehicle operators for drug impairment, and postmortem toxicology.

Workplace drug testing typically involves the analysis of urine samples from job applicants and/or employees to determine whether they have recently used drugs of abuse such as heroin, marijuana, amphetamines or cocaine. Test samples are normally screened by a relatively inexpensive immunoassay, and all presumptively positive samples are submitted for mass spectral analysis to confirm the presence of the drug or drugs. Similarly, for determination of impairment in motor vehicle operators, blood samples are often analysed by mass spectrometric methods to determine whether the impaired performance was associated with recent use of a psychoactive drug. In postmortem toxicology, additional sample matrices are often analysed by mass spectrometric methods in order to gain the greatest insight into whether drugs contributed to the cause of death. In each of these applications the biological specimens must be collected, transported, stored and analysed by procedures that are scientifically and legally supportable.

The application of mass spectrometry in forensic toxicology typically consists of extraction of the drug or drug metabolites from selected body fluids or tissues, chromatographic separation of the drug from other co-extractants, and mass spectrometric detection of the analyte. The chromatographic separation is most often performed by capillary column gas chromatography (GC), following chemical conversion of the analyte to a volatile derivative that has more favourable chromatographic and mass spectral characteristics. The combination of liquid chromatography and mass spectrometry (LC-MS) can also be used, but its adoption by forensic toxicology laboratories has been slow, primarily because of the high cost of LC-MS instrumentation. Nevertheless, LC-MS offers the

important advantages of not requiring derivatization and of being amenable to analysis of high-molecular-mass compounds (such as peptides and proteins) and very polar compounds (such as glucuronide-conjugated metabolites).

GC-MS analyses can be performed using electron ionization (EI) or chemical ionization (CI), followed by either full-scan mass analysis or selected-ion monitoring. Electron ionization is favoured in forensic toxicology because it generates detailed, compound-specific mass spectra, and because more than 100 000 electron ionization reference mass spectra have been published. However, chemical ionization can often provide better sensitivity, depending on the chemical characteristics of the analyte. Most drugs contain basic functional groups that are easily protonated in the gas phase within a chemical ionization source, resulting in a simple mass spectrum dominated by a large protonated molecule (MH^+) ion peak. Drugs that contain functional groups with high electron affinity, such as halogens, can be ionized selectively and with very high efficiency by electron-capture negative-ion chemical ionization.

Figure 1 compares the mass spectra resulting from analysis of a cocaine-containing sample using electron ionization and positive-ion chemical ionization, and illustrates the features typical of these two types of mass spectra. The electron ionization mass spectrum has a relatively low-intensity molecular ion (M^+) peak at m/z 303 and contains many fragment ion peaks. In contrast, the positive-ion chemical ionization mass spectrum shows a single intense peak (m/z 304) that corresponds to the protonated molecule ion (MH^+). The high sensitivity often afforded by chemical ionization is due to the way the analyte ions are concentrated at a single m/z value, rather than being distributed among many different m/z values.

Both full-scan recording and selected-ion monitoring are widely used in forensic toxicology. Each has advantages. A full-scan spectrum that closely matches a reference spectrum generally constitutes the most reliable identification of an analyte. However, monitoring just a few well-selected ions characteristic of an analyte is more sensitive than full-scan recording and can be a reliable identification if it is combined with a selective chromatographic separation.

Figure 1 Comparison of the electron ionization and positive-ion chemical ionization mass spectra of cocaine.

Workplace Drug Testing

The analysis of urine specimens from employees to determine whether they are inappropriately using drugs that can affect job performance falls under the broad category of forensic toxicology because of the legal consequences that can arise. In the United States, workplace drug testing is widely practised, and can be divided into 'regulated' and 'nonregulated' testing. 'Regulated drug testing' refers to programmes that fall under federal regulations, such as the 'Mandatory Guidelines for Federal Workplace Drug Testing Programs' issued in 1988. These 'mandatory guidelines' define how workplace drug testing must be performed, and include the requirement that the testing be performed by laboratories certified by the National Laboratory Certification Program. Another key component of the guidelines requires a two-tier testing process consisting of an initial series of immunoassays followed by confirmatory tests based on gas chromatography–mass spectrometry. For a sample to be reported as positive for a drug, the immunoassay screen must show the presence of a drug class at a concentration above the cutoff values shown in **Table 1** and the GC-MS confirmation assay must show a drug, or metabolite within the drug class, to have a concentration above the cutoff values listed in **Table 2**.

'Nonregulated' workplace drug testing refers to programmes that do not fall under federal regulations. These

Table 1 Initial test cutoffs

Drug class	Cutoff (ng ml ⁻¹)
Marijuana metabolites	50
Cocaine metabolites	300
Opiate metabolites	300
Phencyclidine	25
Amphetamine	1000

Table 2 Confirmation test cutoffs

Drug	Cutoff (ng ml ⁻¹)
9-Carboxy- Δ^9 -THC ^a	15
Benzoyllecgonine ^b	150
Morphine	300
Codeine	300
Phencyclidine	25
Amphetamine	500
Methamphetamine	500

^aThe major urinary metabolite of Δ^9 -tetrahydrocannabinol, the psychoactive component of marijuana.

^bThe major urinary metabolite of cocaine.

programmes may include testing for other psychoactive drugs such as benzodiazepines, barbiturates and lysergic acid diethylamide (LSD). Also, nonregulated drug testing programmes sometimes include analysis of other types of specimens, such as hair or sweat.

Federal regulations do not identify specific methods for performing GC-MS confirmations. However, certain mass spectrometric procedures have become widely adopted by laboratories that perform workplace drug testing. A laboratory must first demonstrate and document that each confirmation assay is specific for the target drug and that it is sufficiently sensitive to permit accurate measurement of the drug at its established confirmation cutoff.

Typically, an analytical batch of urine samples will include each of the following: (1) calibration standards with at least one standard at the analyte's cutoff concentration; (2) quality-control samples containing known concentrations of the analyte both above and below the analyte's cutoff; (3) a sample blank containing none of the analyte; and (4) the test samples submitted for confirmation. A specific amount of internal standard is added to each of these samples. Deuterium-labelled analogues, now commercially available for all common drugs of abuse, are generally the first choice as internal standards. After addition of the internal standard, each sample is extracted to separate the analyte from other components of the urine. This step may involve a simple liquid–liquid extraction with a water-immiscible organic solvent, extraction onto a solid adsorbent and elution with an organic solvent, or a combination of these procedures.

Table 3 Examples of derivatization procedures for GC-MS analysis of common drugs of abuse

Drug group	Derivatization procedure
Amphetamines	Acylation with acid anhydrides such as trifluoroacetic anhydride (TFAA), pentafluoropropionic (PFPA) or heptafluorobutyric anhydride (HFBA)
Opiates	Trimethylsilylation with bis(trimethylsilyl)trifluoroacetamide (BSTFA) or acylation with a fluorinated anhydride
9-Carboxyl- Δ^9 -THC	Trimethylsilylation with BSTFA or alkylation with methyl iodide in dimethyl sulfoxide
Benzoylcegonine	Trimethylsilylation with BSTFA
Benzodiazepines	Trimethylsilylation with BSTFA
Barbiturates	Alkylation with trimethylanilinium hydroxide (TMAH)

Most drugs and metabolites are chemically converted to more volatile and stable derivatives before GC-MS analysis. **Table 3** gives examples of derivatizations commonly used for GC-MS confirmation of drugs of abuse.

Before any test samples are analysed, the mass spectrometer's mass calibration is checked by analysis of a reference material such as perfluorotributylamine (PFTBA), and the measured mass-to-charge (m/z) values for the major PFTBA ions are compared with the corresponding theoretical m/z values. A reference solution containing a known concentration of the analyte or analytes of interest is then injected into the GC-MS system to evaluate the instrument's performance. If the analyte's peak intensity, retention time and chromatographic peak shape are acceptable, analysis of a batch of samples can be initiated.

Fused-silica capillary gas chromatographic columns are universally used for analysis of drugs in forensic laboratories. Typically the columns are coated to a thickness of approximately 0.3 μm with relatively nonpolar methylsilicone or phenylmethylsilicone adsorptive phases and have internal diameters of 0.2–0.3 mm and are 10–30 meters in length. Extracted and derivatized samples injected into the GC-MS are most often detected by electron ionization and selected-ion monitoring (SIM) of three prominent analyte ions and two prominent internal standard ions. The analyte concentration is determined by reference to a calibration curve based on a plot of the ratio of the area of the analyte's quantitating ion to the area of the internal standard's quantitating ion versus analyte concentration. For a urine sample to be confirmed as positive for a drug, the analytical results must meet all of the following criteria:

1. The drug's measured concentration must be equal to, or greater than, the established cutoff concentration for the drug (see **Table 2**).
2. The ratios of peak areas for the monitored ions of the analyte and internal standard must fall within 20% of the corresponding peak area ratios for the calibration standard at the cutoff concentration.
3. The retention times for the analyte and the internal standard must be within 2% of those for the cutoff calibrator.
4. The chromatographic peaks for the analyte and the internal standard must be clearly separate from co-eluting compounds.

The analytical methods most widely practised in laboratories for workplace drug testing have been well validated and are highly reliable. However, some problems continue to be of concern. For example, ingestion of certain legitimate food products can result in a urine sample testing positive for a controlled drug. Poppy seeds, widely used in bakery products, contain low concentrations of morphine, and hemp oil contains low concentrations of Δ^9 -tetrahydrocannabinol, the psychoactive component of marijuana. Efforts to develop analytical methods for testing urine that would permit distinction between ingestion of these food products and nonmedical use of regulated drugs have so far been unsuccessful. However, methods are now available for determining whether urine found to be positive for methamphetamine reflects nonmedical use of methamphetamine or legitimate use of 'Vick's Inhaler', an over-the-counter medication which in the United States contains the L-enantiomer of methamphetamine. To make this distinction, the urine must be analysed by a method that can separate and identify each of the optical isomers of methamphetamine. This can be accomplished by derivatizing the extracted methamphetamine with a chiral derivatizing reagent such as *N*-trifluoroacetyl-L-prolyl chloride. This reaction forms separate diastereoisomers of D- and L-methamphetamine that are easily distinguished by GC-MS analysis.

Testing of Motor Vehicle Operators for Drug Impairment

Drug impairment of operators of motor vehicles (cars, buses, trains, airplanes, etc.) is a continuing threat to public safety. To counteract this threat there has been increased effort devoted to developing analytical methods for determining when an operator's impaired performance is due to use of psychoactive drugs. These analytical methods have also played an important role in investigations into how drugs of abuse, as well as some legitimate prescription drugs, can affect a person's ability to operate a motor vehicle safely. To better understand how drugs can affect human performance, controlled clinical laboratory experiments are required. These experiments are designed to record self-reported

impairment and to detect physiological, perceptual and cognitive drug-induced changes that may impact the subject's performance. The most useful clinical-study designs incorporate collection of biological samples at predetermined times for measurement of the drug concentration. Here mass spectrometry is used extensively to quantify the studied drug and its metabolites. Drug concentrations can then be compared to the physiological and performance measures to determine whether a dose-response relationship exists for the drug being evaluated. These clinical studies provide invaluable data for assisting in interpreting cases with legal implications.

Mass spectrometry is also used to analyse biological samples collected from subjects suspected of operating a motor vehicle under the influence of a drug. In contrast to workplace drug testing, where urine is the body fluid normally analysed, blood is the preferred body fluid for determining impaired performance. This is because drug concentrations in blood have been found to correlate better with the level of impairment at the time the blood was collected than drug concentrations in urine, which can vary widely depending on the subject's degree of hydration and other variables. For some drugs, collection and analysis of saliva can also be an effective method for determining impairment.

Alcohol is the drug most frequently associated with driving impairment, but its presence in the body is measured by a breathalyser or by analysis of blood using procedures that do not require the use of mass spectrometry. Analysis of blood or saliva for other drugs normally includes an initial screening procedure based on a series of immunoanalyses or by a chromatographic screening method, followed by confirmation and quantitative measurement of the drug by mass spectrometry in combination with gas or liquid chromatography.

The frequency with which specific drugs are detected in impaired motor vehicle operators varies from one country or region to another. In the United States, marijuana is the second most frequently detected drug in impaired drivers, with cocaine probably the third most frequently detected. Benzodiazepines have been shown to affect fundamental driving skills such as coordination and reaction time, and are reported to be frequently detected in drivers suspected of being drug impaired. Amphetamines and chemically related sympathomimetic drugs are sometimes used to reduce fatigue in drivers, but large doses of these drugs may lead to greater risk-taking and aggressive driving. Other drugs that have been detected in motor vehicle operators suspected of driving under the influence (DUI) include opiates, barbiturates, antihistamines and antidepressants.

The confirmation and quantitation of drugs identified in DUI cases is a challenge to the forensic toxicologist because drug concentrations are typically lower in blood than in urine or in tissue samples. The determination of

marijuana use by DUI suspects is particularly challenging. Although Δ^9 -tetrahydrocannabinol (THC) and its major metabolites may be detected in blood following recent use, the concentrations of these analytes are usually in the low nanogram per millilitre range. THC and its metabolites have active hydroxyl or carboxyl groups that require derivatization prior to GC-MS analysis. Examples of derivatization procedures are shown in **Table 3**. GC-MS with electron ionization may be used for the analysis of THC and its metabolites, but this combination has limited use in forensic cases because it lacks sufficient sensitivity to routinely measure these analytes in blood samples. Better sensitivity can be achieved using GC-MS with negative-ion chemical ionization following conversion of the cannabinoids to derivatives containing electron-capturing substituents. Sub-nanogram-per-millilitre detection limits have also been achieved by trimethylsilylation of the extracted cannabinoids followed by gas chromatography coupled to a tandem mass spectrometer operated in the positive-ion chemical ionization mode.

Cocaine is rapidly metabolized, primarily to benzoylecgonine and ecgonine methyl ester, and this conversion can continue after the blood is drawn unless an esterase inhibitor such as potassium fluoride is added to the blood immediately. This step is important because the blood concentration of the parent cocaine is a better indicator of the degree of impairment than the concentrations of the inactive metabolites.

Mass spectral identification and quantification of benzodiazepines in blood is complicated by the large number of prescription benzodiazepine drugs available to the public. Treatment of blood extracts with strong acid has been used to convert benzodiazepines to benzophenones, which are more easily identified by GC-MS analysis. However, more recently developed methods using GC-MS with negative-ion chemical ionization or LC-MS with electrospray ionization take less time and offer better sensitivity.

Postmortem Toxicology

Postmortem forensic toxicology involves the analysis of drugs and poisons in body fluids and tissues collected from victims that have died under suspicious circumstances. Postmortem forensic toxicology is a key part of a death investigation in that it can provide information addressing the following questions and issues: (1) What drugs or toxins are present in the body? (2) Are the concentrations of the drugs or toxins in the lethal range? (3) Could drugs have caused impairment resulting in a fatal accident?

Currently in the United States there are no federally mandated regulations governing postmortem forensic

toxicology. However, several forensic toxicology accreditation programmes have been established, and the Society of Forensic Toxicology and the American Academy of Forensic Sciences have published guidelines for forensic toxicology laboratory procedures and performance.

Unlike workplace drug testing, in which urine samples are analysed for a relatively small number of drugs and drug metabolites, postmortem forensic toxicology often involves analysis for a wide variety of drugs and poisons in many different specimens, including gastric contents, vitreous humor, blood, liver, spleen, muscle and brain tissue. Analysis of blood is particularly important because drug concentrations in blood that are high enough to cause death are known for most drugs. However, drug concentrations in blood are generally lower than in urine or in tissues.

Before extraction and analysis, tissues must be homogenized. Water or buffer solutions such as 0.1 M sodium phosphate, pH 6, are added to the tissue sample prior to homogenization. It is important to record the weight of the tissue and the volume of the fluid in which the tissue is homogenized. This information will be used to express the amount of drug per gram of tissue.

Extraction efficiency and sample cleanliness can be a particular challenge in the analysis of postmortem samples because the samples are often collected from decomposed bodies. Products from decomposition can reduce the extraction efficiency and can produce interfering peaks. Also, tissue homogenates contain lipid material that must be separated from the drug analyte prior to GC-MS analysis. Basic drugs can be efficiently separated from lipid material by back-extraction. In this procedure the drug is extracted from the tissue homogenate into a water-immiscible organic solvent and then back-extracted into a dilute acid solution while the neutral lipid material remains in the organic solvent. The dilute acid solution is then made basic and the drug is re-extracted into an organic solvent.

Another cleanup procedure is to reconstitute the initial extract residue in a mixture of hexane and ethanol–water (80:20 v/v). Most drugs will partition into the ethanol–water layer and lipid compounds will partition into the hexane layer. Precipitation of proteins from the tissue homogenates prior to extraction is also helpful for improving cleanliness of the extract and increasing the extraction efficiency. Reagents that precipitate proteins include acetonitrile, methanol and trichloroacetic acid. Digestion of tissue samples with proteolytic enzymes such as subtilisin A can also enhance the recovery of drugs in the extraction procedure.

Following extraction, the analyte is derivatized, if necessary, and analysed by GC-MS. As discussed previously, electron ionization continues to be favoured. However, use of chemical ionization is increasing because

Figure 2 Comparison of the electron ionization and positive-ion chemical ionization mass spectra of cyclobenzaprine and amitriptyline.

it often provides better sensitivity. Also, a chemical ionization mass spectrum will frequently provide valuable complementary information. For example, **Figure 2** shows electron ionization and chemical ionization mass spectra for two similar drugs, amitriptyline and cyclobenzaprine. The electron ionization mass spectra for the two drugs are virtually identical owing to the prominence of the common fragment ion at m/z 58. The positive-ion chemical ionization mass spectra show protonated molecule ion peaks that differ by two daltons, thereby permitting identification of the two drugs.

Of course, the relevant questions in a death investigation cannot be answered by mass spectrometric analysis and other analytical data alone. Final interpretation should always include careful consideration of all the information relating to the case.

Future Developments

The combination of gas chromatography and electron ionization mass spectrometry will continue to be an important analytical tool for identification and quantification of drugs and toxins in most forensic toxicology laboratories. However, the use of liquid chromatography with mass spectrometry has increased and is now the most widely used method for identification and quantification of drugs and other toxins in forensic toxicology

samples. Many variations of liquid chromatography, such as capillary electrophoresis (CE) and capillary electrochromatography (CEC), have been successfully coupled to mass spectrometers and will provide the forensic toxicologist with an array of techniques that will permit many analytical tasks to be performed with improved sensitivity, accuracy and efficiency.

Introduction

Analytical methods of atomic spectroscopy have been used in forestry and wood product research since their earliest development. Nowadays, almost all of the spectroscopic techniques available are employed in the analysis of metals and trace elements in diverse samples of industrial and environmental origin. The techniques that find most regular application include flame atomic absorption spectroscopy (F-AAS), graphite furnace atomic absorption spectroscopy (GF-AAS), inductively coupled plasma atomic emission spectroscopy (ICP-AES) and, occasionally, also direct current plasma atomic emission spectroscopy (DCP-AES). In many applications F-AAS is a sufficiently sensitive and precise technique; however, in the analysis of some environmental samples for trace elements (forest soils, plant material and water) where concentrations may be very low (of the order of 100 ng ml^{-1}) the greater sensitivity of GF-AAS and ICP/DCP-AES is required. In considering the applications of atomic spectroscopy to forestry and wood products it is worthwhile remembering that the analytical method available for use is often determined by the volume and variety of analyses carried out in individual laboratories.

Atomic Spectroscopic Techniques in Use

F-AAS is probably the most widely used analytical method in forestry and wood product research for two reasons. Firstly, it is a long established technique, machines are relatively cheap and widely available and many of the analyses routinely performed by this method have now been optimized. Secondly, the concentrations of many nutrient elements that are important for forest growth, which are present in soil and water (e.g. Ca, Mg, Al, Fe, K, Si) and in wood treated with metal-containing preservatives (Cu, Cr, As, Zn), are well within the limits of detection (100 ppm) of the technique. Environmental samples of this kind are also usually available in large quantities. F-AAS offers a precise, rapid method of analysis, and automation is possible for large numbers of samples.

GF-AAS, also known as electrothermal atomization atomic absorption spectroscopy (ET-AAS) or heated graphite atomizer atomic absorption spectroscopy

(HGA-AAS), is widely available in research analytical laboratories where trace element work is carried out. GF-AAS is possibly the most sensitive method available in the atomic spectrometry range but machines are approximately twice as expensive as F-AAS set-ups. The detection limit for determinations is typically in the order of $10\text{--}100 \text{ ng ml}^{-1}$. Elements in soil/water samples most commonly determined by GF-AAS might include Ca and Mg, but also, in particular, toxic Cd, Cr, Cu, Ni and Pb. Details of the furnace program (the temperature, ramp, hold and purge gas flow characteristics of the drying, charring, atomization and cleaning steps) should be reported in published results more often than they are. The heightened sensitivity of this technique requires the careful use of analytical reagents to keep background contamination to a minimum. Matrix matching between samples and calibration solutions is critical in GF-AAS, and matrix modification (through the addition of ammonium nitrate, magnesium nitrate or palladium salts) may be necessary to prevent the loss of analytes before and in the atomization stage.

When DCP/ICP-AES becomes cheaper and therefore more widely available, the advantages offered by simultaneous multielement determinations combined with detection limits comparable to those of F-AAS (100 ng ml^{-1}), the technique will undoubtedly find greater application in the analysis of forestry and wood samples.

Forestry

Forestry research embraces both the monitoring of environmental impacts on forest ecosystems as well as the impact of forestry on surrounding landscapes, in particular on water catchments. Studies carried out have analysed soil to monitor the effects of acid rain on forest nutrition in relation to observed disease susceptibility in trees from different geographical locations. It is postulated that immobilization of essential plant nutrients such as calcium and magnesium occurs in soil where toxic aluminium becomes increasingly mobile owing to the reduced soil pH attributed to acid rain. Routine monitoring of water catchments that surround forestry follows the level of movement of both nutrient elements (N and P) and other forest exudates (Mn, Cu, Zn, Sr and Ba) in

run-off. Both F-AAS and GF-AAS are used in these analyses and offer acceptable sensitivity and precision.

Wood and Wood Products

Timber harvested from commercial forests has several possible end users. Good quality timber (i.e. timber with good growth characteristics) is sawn to produce timber for the construction industry. Nonconstruction grade timber can end up being processed to make wood pulp and ultimately paper or used as sawn timber, joinery, fencing rails and posts, transmission poles, bulkheads and pilings. More recently, poorer quality timber has been used more and more to make value added commodities such as board materials like medium density fibre board (MDF), oriented strand board (OSB) and particle/chip board. Each of these areas generates the need for further monitoring for various reasons.

The awareness of the need to monitor paper and pulp mill effluent is not novel. The reduction, and even elimination, in the use of chlorine in the bleaching of pulp has focused environmental concern on the other elements present in wood pulp. Pulp and paper mill effluent may contribute to elevated metal concentrations in receiving waters and sediments. Consequently, the wood pulp industry, along with statutory monitoring bodies, makes regular use of sensitive and quantitative techniques such as DCP-AES and GF-AAS in attempts to reduce metal levels.

The implication of wood dust and the metals from machined treated wood in the increased incidence of carcinoma in people working with wood also requires the use of GF-AAS and F-AAS in the health and safety analysis of dusts from wood-related work places (joinery manufacturers, sanding and sawing operations, particle board and plywood industries).

Wood Preservatives

The bulk of analytical work performed in the wood sector is associated with wood preservatives. Most temperate timbers are perishable and therefore require treatment with toxic combinations of elements to achieve protection from biodeterioration owing to attack by fungi, insects, termites and, in marine situations, wood-boring crustaceans and molluscs.

The most widely used preservatives are the class of inorganic waterborne salts that contain Cu, Cr, As, B and Zn. A list of commonly used preservatives of this type is presented in Table 1.

Preservative Penetration and Retention

The necessity of monitoring the levels of preservatives (waterborne inorganic salts as well as organic

solvents and creosote) in treated timber arises from the fact that such timber is supposed to be treated to specified levels or retentions (kg preservative salt m^{-3} wood), depending on the biological hazard to which it is expected to be exposed in service. There are five classes of biological hazard based on the expected exposure to wetting and these are shown in Table 2.

Technical standards exist which prescribe the levels of preservative salt necessary in timber exposed to a given hazard class. Treatment levels are defined in terms of required penetration depths and must be matched to individual wood species' treatability. The more pertinent European and American standards covering these technical requirements are listed in Table 3.

Meeting the requirements of these standards generates an enormous amount of routine analysis in the preservative treatment plants that are responsible for correctly treating the timber, and also in research laboratories examining biodeterioration of timber and in industrial development laboratories. Inorganic waterborne elements are readily determined using F-AAS and this is the method recommended in the technical standards governing the analysis of inorganic waterborne preservatives, the European and American examples of which are included in Table 3.

Naturally Occurring Levels of Elements

The naturally occurring levels of the elements most frequently analysed in forestry soil and foliage samples and wood/wood product samples are presented in Table 4. The normal manner in which samples containing these elements are prepared so as to release the element as an analyte for trace element determination is indicated in the table. Where several analytical techniques are possible this is indicated in the footnotes. The most commonly recommended F-AAS and GF-AAS settings for the same elements are shown in Table 5 along with potential interferences and their control. From these two tables it is readily appreciated that, for most determinations involving forestry related or wood samples, contamination is not usually problematic and background levels can frequently be ignored.

General Instrument Settings

Sample instrument settings for F-AAS, GF-AAS and ICP-AES analyses are shown in Table 6. However, instrument manufacturers' recommendations should always be followed.

Table 1 Common inorganic waterborne salt type wood preservatives; active ingredients and nominal compositions as well as the recommended in-service situation are listed

<i>Preservative</i>	<i>Active ingredient</i>	<i>Nominal % composition</i>	<i>Principal use/country of use</i>
Chromated zinc chloride (CZC)	Zinc as ZnO	80	Out of ground contact USA, Germany

Table 2 Biological hazard classes for timber exposed in service as defined by the European Standard EN 335-1:1992

<i>Hazard class</i>	<i>General service situations</i>	<i>Description of wetting in service</i>	<i>Occurrence of biological agencies^a</i>			
			<i>Fungi</i>	<i>Beetles^b</i>	<i>Termites</i>	<i>Marine borers</i>
1	Above ground, covered (dry)	None	–	U	L	–
2	Above ground, covered (risk of wetting)	Occasionally	U	U	L	–
3	Above ground, not covered	Frequently	U	U	L	–
4	In contact with ground or fresh water	Permanently	U	U	L	–
5	In salt water	Permanently	U	U	L	U

^aU, Universally present within Europe. L, Locally present within Europe.^bThe risk of attack can be insignificant, according to specific service situations.

Analytical Procedures

General Comments

In the use of AAS or AES, quality control can be maintained by the use of standard reference materials in analyses. Although expensive, the practice of including

reference samples provides extra control to the data generated. The heterogeneity of elemental distributions in ecological samples requires adequate field sampling to generate a statistically significant number of samples on which accurate determinations can be made. In many instances the pooling of samples after initial processing

(grinding, drying, sieving, etc.) is possible (and has been reported for soils and herbaceous plant matter) but the decision must be made whether to sacrifice the spatial pattern for a mean concentration. The practice is not recommended for wood. Matrix matching of calibration and test solutions is critical, especially where the more sensitive GF-AAS is concerned. If acid digests have been carried out on samples, the same acids must be used in calibration standards. Analytical grade chemicals should be used in all determinations and, where specified, distilled and deionized water may be preferred over distilled water.

Applications of Atomic Spectroscopy in Forestry and Wood Products

Fine Estuarine Sediments

Particulate organic matter (POM) is largely associated with fine sediment fractions, i.e. silts (2–20/50 µm) and clays (<2 µm). Inorganic copper–chromium–arsenic salts (CCA) leached from submerged or floating treated wood in coastal situations also tend to be associated with the organic matter in this fraction. The settlement of fine particulates (POM, silts, clays) where Cu, Cr and As may be present is dependent on the flushing characteristics of the water body as well as the age of the structure from which preservative components are leaching. In slow currents where recently treated timber is present, Cu, Cr and As can be detected several metres from treated wooden emplacements such as pilings, floating jetties and bulkheads. It is important that experimental design takes these facts into account when deciding on a sampling regime.

Fine sediments should be allowed to settle out in volumetric cylinders before subsampling so as to reduce the risk of contamination from metal sieves. Sediment is then dried (150 °C) and a subsample wet ashed in a 3:1 mix of nitric acid and perchloric acid (HNO₃–HClO₄). *Caution:* perchloric acid is highly explosive when it comes into contact with organic matter. Therefore raw organic samples should always be pre-mixed in warmed nitric acid *before* the addition of perchloric acid. Once perchloric acid has been added, the digest mix should not be allowed to boil dry. Only experienced personnel should handle and store this reagent.

Determinations of Cu, Cr and As can be made on the filtered liquid fraction, using the recommended settings in the manual accompanying the atomic spectrometer used. Elemental levels determined by F-AAS methods from fine coastal sediments have been found in the range 25–2000 µg Cu per g sediment, 40–180 µg Cr per g sediment and 10–100 µg As per g sediment. The possibility of carrying out hydride generation before the determination of arsenic is an option on many machines.

Algae and Animal Tissues

Plant and animal material (e.g. algae, crustaceans, molluscs and bivalves) collected to determine the transfer of metals from the environment to biota within habitats can be collected at field sites and frozen until laboratory analysis is possible. Defrosted or fresh material can then be oven dried (150 °C) before a subsample is selected and wet ashed in a 3:1 mix of nitric and perchloric acid (HNO₃–HClO₄). Note the cautions expressed above for the handling of this mixture.

The filtered leachate is analysed in F-AAS using the settings recommended by the manufacturer of the

Table 4 List of common soil minerals and methods for sample preparation and analysis; naturally occurring levels (in mineral soils, freshwater, etc.) are also included. Hold (s)	15	30	4	4
Purge gas flow	Low	Medium	None	High

^aMaximum power heating.

These conditions represent improved optimization compared with conditions recommended in manufacturers manual for Al determination.

machine for each element under determination. In cases where the elemental concentrations are likely to be very low (e.g. control samples from 'clean' sites) it may be necessary to carry out analysis using GF-AAS (or ICP-AES if available) with a simpler acid digestion. Typical levels of CCA encountered in coastal biota where preserved wood is submerged are in the range $5\text{--}10 \mu\text{g g}^{-1}$ (As) $5\text{--}15 \mu\text{g g}^{-1}$ (Cr) and $60\text{--}150 \mu\text{g g}^{-1}$ (Cu).

Trees and Herbaceous Plant Material

Foliage samples are collected fresh and then stored cold or frozen until analysis. Dried/defrosted samples are oven-dried at $60\text{--}80^{\circ}\text{C}$ and then ground to a fine powder in a suitable mill. Beware: steel mills may lead to contamination by Fe, Mn, Mo and Co while other mills can lead to contamination by Cu and Zn. Ceramic ball mills may lead to contamination by Al, B, Ca, K or Na.

Ground samples are dissolved in a wet digestion procedure on a heating block using a 3:1:2 mix of $\text{HNO}_3\text{--H}_2\text{SO}_4\text{--H}_2\text{O}_2$ (typically $1\text{--}5 \text{ g}$ in $1.5:0.5:1.0 \text{ mL}$ of acid mix). Lanthanum (as lanthanum chloride, $1000 \mu\text{g mL}^{-1}$) is added as a releasing agent to prevent phosphate interference in the analysis of Ca and Mg by F-AAS. Aluminium levels may need to be determined by the more sensitive GF-AAS, in which case the chances of contamination need to be minimized by using smaller

volumes of acid in the digestion mix (1 mL HNO_3 , $0.2 \text{ mL H}_2\text{SO}_4$, $0.2 \text{ mL H}_2\text{O}_2$).

Forest Soils

Soils are collected in the field using stainless steel soil probes which sample to depths of $40\text{--}50 \text{ cm}$, maintaining the stratigraphic integrity of the sample. Before analysis soil may be split into different levels, most metals are associated with the organic fraction in the active root zone $10\text{--}15 \text{ cm}$ down. Soil should be air-dried for several days (~ 7) and then ground in a mortar and pestle and passed through stainless steel (2 mm) and 1 mm mesh sieves. After thorough mixing, soils can be stored in polythene bags until analysed.

Available nutrient elements are extracted from $\sim 2 \text{ g}$ subsamples which are treated with ammonium acetate (100 mL) and placed on a mechanical shaker for 1 h and then the resulting solution is gravity filtered. Concentrated HCl can be added ($2\text{--}3$ drops) to decrease the bacterial activity in the sample. Lanthanum (as lanthanum chloride at $1000 \mu\text{g mL}^{-1}$) is added to the filtrate so as to prevent the interference of phosphate in the determination of Ca and Mg. Soil element concentrations are usually determined by F-AAS. Certain micronutrients such as Mo occur at levels near the limits of detection of F-AAS and are best

Table 7 Naturally occurring metal ion concentrations in wood of various kinds; values on a mg per kg dry weight basis

Source	Na	Al	Fe	Mn	Zn	Cu	Pb	Cd	Cr	B
Spruce	76–133	3.2–8.3	1.6–3	32–271	5.7–22.9	0.7–1.3	0.3–1.5	0.2–0.5		
Birch	96	11	21	76						
Pine	35	16	24	76						
Hardwoods						0.2–2.1			0.2–4.6	1.5–7.2
Softwoods						0–3.0			0.2–4.8	0.8–6.8

determined by GF-AAS. Naturally occurring levels of Cr, Pb and Ni are also best determined by the more sensitive GF-AAS. Only chromium absorbance experiences potential interference, from Ca and Fe, which is controlled by several means, including the addition of 2% ammonium chloride (NH_4Cl) to samples and standards.

Solid Wood

The analysis of solid wood for elements (both naturally occurring and as preservative components) is a relatively straightforward determination using spectroscopic techniques. Some values for naturally occurring elements in hardwoods and softwoods are presented in **Table 7**; the levels of toxic metals reported for spruce are noteworthy. The methodology detailed here for the analysis of wood preserving elements is widely accepted.

Only Ca, Mg and phosphate are reported to occur in appreciable amounts in wood and experiments carried out in the presence of excess Ca, Mg and phosphate showed no interference in typical digest mixes [0.5 M sulfuric acid and 0.3% (w/v) sodium sulfate] in the determination of Cu, Cr, As and Zn. Phosphate does not interfere with As determination, indicating that an insignificant amount of the phosphate present is ionic. Good extractives are not reported to cause interference in the determination of Cr and Cu and they can enhance the As signal unless the burner height is maintained between 1.3 and 1.5 cm (1.4 cm is frequently used). There is no interelement interference in the determination of Cu, Cr and As solutions. Preservative compounds are extracted from treated wood prepared as thin sections (0.2 mm thick), sawdust (produced by sawing a suitably representative part of the treated wood) or wood flour (prepared by hammer milling wood chips).

The decomposition step is carried out in a mixture of 0.5 M sulfuric acid and 100 volume hydrogen peroxide. The copper (II) sulfate, potassium/sodium dichromate and arsenic pentoxide in CCA preservatives undergo fixation to form potassium / sodium sulfate by-products. Any potential interference in the chromium and arsenic signals from these compounds in the leachate is overcome by an excess of sodium sulfate (at 0.3% w/v) added to samples and calibration standards. Wood that has been submerged in water for a prolonged period can experience leaching of preservative salts and so the

concentration of potassium/sodium salts in treated wood can be very variable.

The analytical sensitivity for arsenic has been improved from $0.60 \mu\text{g ml}^{-1}$ to $0.10 \mu\text{g ml}^{-1}$ by the use of an argon–hydrogen flame (instead of air–acetylene) and a 10 cm propane burner (instead of a 10 cm acetylene burner) analysed at a wavelength of 197.2 nm, and this flame is recommended in arsenic analysis. The argon–hydrogen combination is highly explosive and should only be used by trained personnel.

Standard curves can be prepared in the range of $5\text{--}35 \mu\text{g ml}^{-1}$ Cu and $10\text{--}70 \mu\text{g ml}^{-1}$ Cr and As for preservative concentrations in the region of 3% w/v. The acid decomposition described is suitable for samples in the range of 3–8 g.

The comminution of wood probably represents the most time-consuming part of the sample preparation procedure. The production of wood flour requires the tedious reduction of wooden samples to a small enough size (*ca* matchstick) before feeding into a hammer mill. The hammer mill itself can be a cause of contamination in the form of Cr or Cu from the hammers or the chamber though this is probably insignificant compared with the levels of Cu and Cr in the treated wood. Though wood flour represents the maximum surface area to volume ratio for the action of the acid decomposition, the use of thin wood sections (0.2 mm thick) or sawdust is acceptable providing they are obtained from areas of treated wood deemed representative of the whole, i.e. not from the ends or surfaces, which can be over-treated with respect to the rest of the timber.

Water

The requirements of the analysis of water from various sources is one area of environmental research that is driving efforts to improve the limit of detection of spectroscopic analysis. Elements are frequently in very dilute concentrations and the presence of dissolved salts (chiefly sodium chloride and magnesium salts in marine samples) can offer some interference in sensitive analyses.

The pulping of hardwood and softwood during the manufacture of paper generates waste water that contains elements such as P and metals such as Na, Al, Mn, Fe, Zn, Cd, Cu, Cr, Ni, Hg and Pb. These elements and metals are released in mill effluent to receiving waters and

elevated concentrations can build up in fine sediments at some distance (up to 12 km) from the effluent source.

Water samples can be handled in several ways but an important precaution is to prevent the sorption of metals to sample bottles. This is achieved by the addition of 0.02 vol.% suprapure nitric acid. Both plasma AES and GF-AAS methods are suitable for the determination of the elements mentioned. Wavelengths (nm) considered more sensitive for elements in organic matrices analysed by DCP-AES include 568.82 (Na), 308.215 (Al), 259.94 (Fe), 403.076 (Mn) and 202.548 (Zn).

The determination of Cr, Ni and Pb requires the addition of $\text{NH}_4\text{H}_2\text{PO}_4$ to samples for matrix modification. Most elements in pulp effluent occur in $\mu\text{g l}^{-1}$ concentrations (As, Ba, Co, Li, Sr, Sn) while some, such as Na, Ca, Mg, Si and K (naturally present in wood or added to pulp during processing in various chemicals), occur in mg l^{-1} concentrations. Mass spectrometry may be employed for certain elements that are present in very low concentrations of $<1 \mu\text{g l}^{-1}$ (Ag, Mo, Sb, Tl) and the combination of elements determined by this method offers a characterization of pulp and paper mill effluent in water. Mercury is determined by cold vapour AAS where the detection limit is $\sim 0.1 \mu\text{g-Hg l}^{-1}$.

Air

The concentration of metals in the air of wood-processing factories has become a more prominent health and safety issue and the analysis of metal-containing dust samples is carried out by AAS and AES methods.

For the analysis of metal elements in the air of factories that process wood which has been treated with wood preservatives (such as Cu, Cr and B) the finest dust particles are collected by suction onto glass fibre filter paper. The concentration of dust (in mg m^{-3} air) is calculated by dividing the mass of the dust (mass of filter paper after filtering minus the mass of filter paper before filtering) by the volume of air filtered.

Elements are determined in dust by first drying the dust sample over silica gel. Fine dust samples are very mobile and difficulties may be experienced transferring samples. A dust sample is leached in 20 ml HNO_3 (1 M) mixed with 1 ml H_2O_2 (30%) in an Erlenmeyer flask and shaken on a mechanical shaker for 20 h. After filtration, Cu and Cr determinations may be made using F-AAS as described above.

Hexavalent chromium (the more toxic form of Cr) can be determined separately by extraction from dried dust with diphenylcarbazide followed by photometric analysis. Boron is extracted from silica gel dried dust by leaching in the HNO_3 (1 M) mix described above. After 20 h in the solution on a mechanical shaker the sample is filtered, extracted with 2-ethylhexa-1, 3-diol and curcumin and analysed by photometry.

To date, research has shown that in less than half of the workplaces examined the concentration of dust in workplace air was above the recommended threshold ($2 \text{ mg dust per m}^{-3}$ of air), and in fewer than a third of cases the levels were five times the recommended threshold value. It has also been shown that the concentration of metals in the dust did not have its origin exclusively in preservative treated wood but that there was a significant load of metals from external air. The concentration of hexavalent chromium in dust was in line with natural levels in air and well below the safe threshold levels of $50\,000 \text{ ng m}^{-3}$.

Future developments

Analytical improvements in atomic spectroscopy are most likely to affect the analysis of water and air samples related to environmental impacts of wood products and the health and safety aspects of working with wood and wood preservatives. Atomic absorption spectrometry is now such a thoroughly tried and tested analytical technique that regular major advances are unlikely.

In spite of the advent of ICP-based techniques, F-AAS and GF-AAS continue to be used routinely in many laboratories for the analysis of waters, soils and plant material. As might be expected, most of the significant developments in the AES field have been associated with ICP-AES, and especially with aspects of sample introduction to the ICP, though reports of novel developments in wood-related research are not plentiful.

Symbols

A_0	average of $v(t)$ over T
A_k	amplitude of cosine components of frequency k/T
f_k	sinusoid frequency (k th harmonic)
T	signal time period
$v_c(t)$	continuous time signal
$v_c(\pm)$	continuous time signal
$v[n]$	discrete sequence
$v(t)$	periodic signal
$V(\omega)$	Fourier transform of $v(t)$
θ, ξ	angular frequency
ϕ	phase of complex sinusoid
ω	the radian frequency $2\pi f$
Ω_0	frequency of a discrete sinusoid

In Fourier transform spectroscopy (FTS), the output of the detector can be represented as a value that is a function of the independent variable, usually time. For a given finite measurement time T , it can be considered a transient signal that lasts T seconds. This transient is the interferogram in FT-IR or the free induction decay in FT-NMR. In either case, this transient function contains all the spectral information being measured, but the spectral amplitude for each frequency is encoded in the detector signal and in general is not discernible directly. The Fourier transform is a mathematical operation that can be used to change this function of time into an amplitude that is a function of frequency, which is a representation of the desired spectrum.

Signal processing has always been a critical aspect in spectroscopy and especially in FTS. The generalized use of computers as components in spectrometers to implement the Fourier transform and/or other digital signal processing (DSP) tasks requires, as a first step, that the signals used be discrete amplitude, discrete time-sampled representations of continuous amplitude, continuous time (analogue) signals, such as the output of a detector. The sampling process must meet certain minimum requirements for the resulting sample sequence to contain all the information of the original signal. The output of the sampling process is a continuous amplitude, discrete time representation of the original signal. To obtain a discrete

amplitude sequence, the amplitude of each sample is quantized with finite precision by a digital to analogue converter (ADC) and is then represented by a number. The resulting sequence of numbers is the input to the DSP.

The Fourier Series

In the artificial case that the spectrometer measures the same sample multiple times, the successive transients will be identical, and the entire sequence will be a periodic signal of period T .

The Fourier series provides a representation of the signal as a sum of sinusoidal components of different frequencies. For a periodic signal of period T it is easy to visualize that the component frequencies will be $f_k = k/T$, where $k = 0, 1, 2, 3 \dots$, because these sinusoids are the only ones periodic in T . These components are called harmonics of the signal. The sinusoid of frequency f_k is the k th harmonic.

Sinusoids are used to study and represent signals in linear time invariant systems because an input sinusoid generates an output from a linear time invariant system that is a sinusoid of the same frequency. (See Mason and Zimmerman in the Further Reading section.) The Fourier series representation of a periodic signal $v(t)$ with period T is

$$v(t) = A_0 + \sum_{k=1}^{\infty} \{A_k \cos(2\pi k/T)t + B_k \sin(2\pi k/T)t\} \quad [1]$$

for $k = 1 \dots \infty$, and $-\infty < t < \infty$; $2\pi k/T$ is the radian or angular frequency of the k th harmonic and $A_k \cos(2\pi k/T)t$ and $B_k \sin(2\pi k/T)t$ are the harmonic components of $v(t)$. A_k is the amplitude of the cosine component of frequency k/T . A_0 is the average of $v(t)$ over a period T , and A_k and B_k are the averages of $2v(t)\cos(2\pi k/T)t$ and $2v(t)\sin(2\pi k/T)t$ respectively, also over a period T .

For an even function of t , that is $v_e(t) = v_e(-t)$ the above simplifies to

$$v_e(t) = A_0 + \sum_{k=1}^{\infty} A_k \cos(2\pi k/T)t \quad [2]$$

For an odd function of t , that is $v_o(t) = -v_o(-t)$ we have

$$v_o(t) = \sum_{k=1}^{\infty} B_k \sin(2\pi k/T)t \quad [3]$$

The Fourier series can be written in a more compact form with the use of the complex exponential function $\exp(i\omega t) = \cos(\omega t) + i\sin(\omega t)$, where ω is the radian frequency $2\pi f$, and $\omega_0 = 2\pi/T$. Then

$$v(t) = \sum_{k=-\infty}^{\infty} V_k \exp(ik\omega_0 t) \quad [4]$$

where V_k is the average of $v(t)\exp(-ik\omega_0 t)$ over the period T :

$$V_k = 1/T \int_{-T/2}^{T/2} v(t) \exp(-ik\omega_0 t) dt \quad [5]$$

V_k has the dimension of voltage, and in the general case will be complex. This expression leads to the Fourier transform, also called the Fourier integral. If we assume $v(t)$ is periodic with period T , and different to zero for $|t| < T/2$, we can define

$$V(k\omega_0) = \int_{-T/2}^{T/2} v(t) \exp(-ik\omega_0 t) dt \quad [6]$$

$V(k\omega_0)$ has dimensions of voltage per unit frequency. It is independent of T , and does not change when T increases, while the Fourier coefficients V_k become smaller as T increases.

$$V_k = (1/T)V(k\omega_0) = (\omega_0/2\pi)V(k\omega_0) \quad [7]$$

$$\begin{aligned} v(t) &= (1/T) \sum_{k=-\infty}^{\infty} V(k\omega_0) \exp(ik\omega_0 t) \\ &= \sum_{k=-\infty}^{\infty} V(k\omega_0) \exp(ik\omega_0 t) (\omega_0/2\pi) \end{aligned} \quad [8]$$

For T approaching infinity, ω_0 tends to zero, and if we define $\omega = k\omega_0$, in the limit

$$v(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} V(\omega) \exp(i\omega t) d\omega \quad [9]$$

and

$$V(\omega) = \int_{-\infty}^{\infty} v(t) \exp(-i\omega t) dt \quad [10]$$

where $V(\omega)$ is the Fourier transform of $v(t)$. The term $V(\omega)$ is also called the frequency spectrum of $v(t)$ or simply the spectrum. This is the Fourier representation of a single pulse, because we defined it by selecting one pulse and moving all others in the sequence to infinity.

In the case of the periodic signal, the coefficients of the Fourier series have the dimension of voltage. The Fourier transform of a pulse $v(t)$, $V(\omega)$, has the dimensions of voltage multiplied by time, and we can think of it as a voltage density spectrum with a dimension of voltage per unit frequency. Therefore, the area under $V(\omega)$ has the dimension of voltage.

Table 1 lists some of the properties of the Fourier transform. The functions $v(t)$ and $u(t)$ are defined for

$-\infty < t < \infty$, and their respective Fourier transforms $V(\omega)$ and $U(\omega)$ are defined for $-\infty < \omega < \infty$. In property 6 of **Table 1** the convolution is defined for $-\infty < \xi < \infty$, where ξ is the angular frequency. It is used here to distinguish it from the independent variable ω of the result.

Discrete Time Signals and Sampling

In the development of the Fourier transform above we have assumed that the signal $v(t)$ was a continuous time signal defined for $-\infty < t < \infty$. These signals are also commonly called analogue signals.

Discrete time signals may be generated by a discrete time process or may be the result of a sampling process on a continuous time signal.

The common method to obtain a discrete representation of a continuous time signal is to take periodic samples of the signal, and create a sequence $v[n]$ from the continuous time signal $v_c(t)$ defined by the equality

$$v[n] = v_c(nT_s) \quad \text{for } -\infty < n < \infty \quad [11]$$

where T_s is the sampling period, and its inverse, $f_s = 1/T_s$, is the sampling frequency, in samples per second.

The sampling operation is not invertible in general, that is given $v[n]$, it is not possible in general to reconstruct $v_c(t)$ because many continuous signals can be represented by $v[n]$. The sampling theorem due to Nyquist removes this uncertainty by imposing a restriction on the signal $v_c(t)$.

Figure 1a shows a portion of the continuous time signal $v_c(t)$ defined for $-\infty < t < \infty$, and the Fourier transform of $v_c(t)$, the spectrum $V_c(\omega)$. We have chosen $v_c(t)$ such that $V_c(\omega) = 0$ for $|\omega| > f_0$ ($|\omega| > 2\pi f_0$). **Figure 1b** shows a portion of the periodic train of unit impulses $u_p(t)$, defined for $-\infty < t < \infty$, and a portion of

Table 1 Some properties of the Fourier transform

Figure 2 Impulse train converted into a discrete time sequence.

the Fourier transform of $u_p(t)$, the spectrum $U_p(\omega)$, $-\infty < \omega < \infty$.

It is convenient to represent the sampling process in two steps, as shown in **Figure 2**. First the multiplication of $v_c(t)$ with a periodic train of unit impulses $u_p(t)$, which results in the train of impulses $v_s(t)$ for $-\infty < t < \infty$, and second, the conversion of the train of impulses to a sequence of samples $v[n]$.

The product of the continuous signal $v_c(t)$ with the periodic train of impulses generates the train of impulses $v_s(t)$ that is zero except at integer multiples of T_s .

Figure 2a shows a portion of the train of impulses $v_s(t)$ that has a spectrum $V_s(\omega)$ for $-\infty < \omega < \infty$, where ω is the radian frequency $2\pi f$. This spectrum can be obtained using property 6 of the Fourier transform in **Table 1**, which shows that the transform of the product of two functions is the convolution of the transforms. The convolution of $V_c(\omega)$ with the periodic train of impulses $U_p(\omega)$ of **Figure 1** results in periodically repeated copies

of $V_c(\omega)$, separated by $1/T_s$, a portion of which is shown in **Figure 2a**.

Sampling Theorem

The sampling theorem due to Nyquist (see Mason and Zimmermann in the Further Reading section) can be visualized from **Figure 2a**. The sampling frequency, $f_s = 1/T_s$, must be at least twice the highest frequency f_0 contained in the signal; otherwise the spectrum of $V_s(\omega)$ will be corrupted by the overlap of adjacent replicas of $V_c(\omega)$ and it will not permit the recovery of the original signal. When the above condition is met, the spectrum of $V_s(\omega)$ contains all the information of the original spectrum $V_c(\omega)$; therefore the original signal is recoverable from $V_s(\omega)$, for example by passing the sampled signal through a low pass filter that rejects frequencies above f_0 but passes all the frequency components below f_0 .

Sampling at a rate higher than $1/T_s$ has the undesirable effect of increasing the computational cost of any digital signal process that follows. One exception is the case of the recovery of the original signal with a simple filter. The trade off between sampling rate and filter complexity is more common in the case of narrow band signals and analogue filters.

The discrete sequence $v[n]$ for $-\infty < n < \infty$ in **Figure 2a** is indexed on the integer variable n , which does not have information about the sampling rate and represents the samples of $v_c(t)$ with finite numbers instead of the areas of impulses as in $v_s(t)$. The spectrum of $v[n]$ is $V_s(\Omega)$ for $-\infty < \Omega < \infty$, the discrete Fourier transform of $v[n]$, where Ω is in radians.

Discrete Time Signals and the Fourier Transform

A sequence that represents a sinusoid has the general form for $-\infty < n < \infty$:

$$v[n] = A \exp[i(\Omega_0 n + \phi)] \quad [12]$$

By analogy with the continuous time case, Ω_0 is called the frequency of the complex sinusoid, and ϕ is called the phase. Here n is a dimensionless integer number. Therefore, the dimension of Ω_0 is radians. One can specify the units of Ω_0 in radians per sample, for a better analogy with the continuous time case.

A more important difference with the continuous time case becomes apparent when we consider the frequency ($\Omega_0 + 2\pi$). In this case

$$\begin{aligned} v[n] &= A \exp[i(\Omega_0 + 2\pi)n] \\ &= A \exp(i\Omega_0 n) \exp(i2\pi n) \\ &= A \exp(i\Omega_0 n) \end{aligned} \quad [13]$$

It is easy to see that sinusoids and complex exponential sequences that differ in frequency by a multiple of 2π are identical. For these sequences, we only need to consider frequencies in an interval of length 2π , such as $-\pi$ to π , or 0 to 2π .

Discrete time periodic sequences are also different from continuous periodic signals in the behaviour of the frequency of the harmonics. A periodic discrete time sequence can be defined as

$$v[n] = v[n + N] \quad [14]$$

for $-\infty < n < \infty$, where the period N has to be an integer. A periodic discrete time sinusoid sequence,

$$A \cos(\Omega_0 n + \phi) = A \cos(\Omega_0 n + \Omega_0 N + \phi) \quad [15]$$

requires that $\Omega_0 N$ must be a multiple of 2π . Therefore

$$\Omega_0 N = 2\pi m \quad [16]$$

where m is an integer. The same result applies to complex exponential sequences.

A further conclusion from eqns [13] and [16] is that, for a periodic sequence of period N , the only frequencies that can be different are

$$\Omega_m = 2\pi m/N, \text{ for } m = 0, 1, \dots, N-1 \quad [17]$$

Furthermore, low and high frequencies appear differently than in continuous signals. In the discrete time sinusoid $v[n] = A \cos(\Omega_0 n + \phi)$ as Ω_0 increases from 0 to π , $v[n]$ cycles faster, but as Ω_0 increases from π to 2π , $v[n]$ cycles slower and slower, and the sequence for $\Omega_0 = 2\pi$ is the same as the one for $\Omega_0 = 0$.

In general we can define the discrete Fourier transform of the sequence $v[n]$ as

$$V(\Omega) = \sum_{n=-\infty}^{\infty} v[n] \exp(-i\Omega n) \quad [18]$$

that is valid whenever $v[n]$ meets

$$\sum_{n=-\infty}^{\infty} |v[n]| < \infty \quad [19]$$

Using similar reasoning to that used for the continuous time case, we can write

$$v[n] = \frac{1}{2\pi} \int_{-\pi}^{\pi} V(\Omega) \exp(i\Omega n) d\Omega \quad [20]$$

Equations [18] and [20] form a discrete Fourier transform pair that relate the discrete sample space with the frequency space.

Table 2 lists some of the properties of the discrete Fourier transform. The functions $v[n]$ and $u[n]$ are defined for $-\infty < n < \infty$, and their respective discrete Fourier transforms $V(\Omega)$ and $U(\Omega)$ are defined for $-\pi < \Omega < \pi$. In property 5 of **Table 2** the convolution is defined for $-\pi < \theta < \pi$, where θ is the angular frequency. It is used here to distinguish it from the independent variable Ω of the result.

The Cooley-Tukey algorithm is the most common fast Fourier transform (FFT) algorithm. It re-expresses the discrete Fourier transform (DFT) of an arbitrary

Table 2 Some properties of the discrete Fourier transform

	Function	Discrete Fourier transform

Introduction

Melvin B. Comisarow and Alan G. Marshall published a series of papers in 1974 first describing and reporting results of Fourier-transform ion cyclotron resonance (FT-ICR) mass spectrometry (MS). FT-ICR MS to date has the highest mass measurement accuracy and resolution of any mass spectrometry platform. In recent years, Orbitrap mass spectrometers have narrowed the performance gap considerably relative to other mass spectrometers. This is in part due to the many similarities of Orbitrap and FT-ICR mass spectrometers and Fourier-transform mass spectrometry (FTMS) as terminology has come to refer to both of these high-resolution methods.

Occasionally, it has been stated that FT-ICR MS was always going to be the highest performing mass spectrometer. Such statements have been made for a variety of justifications, including that fundamentally FT-ICR MS is about measuring frequencies, a measurement that can be performed with unparalleled precision and accuracy, and FT-ICR MS is inherently a multichannel detection method, meaning all possible ion frequencies are detected simultaneously. There is no scanning across an ion mass-to-charge ratio (m/z) range; all ions are detected at the same time. Thus, the superior FT-ICR MS analytical performance results from the physics and analytical method foundation of the technique.

Theory

Fundamentally, FT-ICR MS measures the frequency of ion motion in a magnetic field, known as cyclotron motion. Movement of ions in a magnetic field generates a radial component of force, which causes a deflection in

the direction of ion motion. Assuming a magnetic field going into this page, the trajectory of a charged ion moving across the page will bend due to forces arising from the magnetic field interacting with the charged particle (**Figure 1**). The force bending the ion motion is known as the Lorentz force. As the ion is still moving, the Lorentz force continues to bend the direction of ion travel. Under suitable conditions of magnetic field and ion mass, charge, and velocity, the trajectory of the ion is bent into a circle, or cyclotron orbital.

The rate at which the ion circles around, or the ion cyclotron frequency, is determined by the magnetic field, ion charge, and ion mass. Once the ion begins the circular cyclotron motion, barring external/additional forces, the ion will remain on the page indefinitely. In practice, this type of spatial confinement is known as ion trapping.

In most FT-ICR MS applications, the ions actually enter the magnetic field in the same direction of the magnetic field, or in terms of our previous example, into the page. The ion will still undergo cyclotron motion, due to the components of ion motion in the plane perpendicular to the magnetic field, for example, the plane of the page. The combination of ion motion into the page and cyclotron motion results in the ion precessing around its axis of motion, into the page, at the ion cyclotron

Figure 1 By convention the magnetic field is defined to align with the z-axis. An ion moving through a magnetic field experiences a force, called the Lorentz force, which bends the trajectory of the ion. Under suitable conditions the trajectory of the ion will bend into a circle. Note, as illustrated, that the velocity, or kinetic energy, of the ion does not change the cyclotron frequency.

Figure 2 The top illustration is a schematic of a cylindrical ICR trapping cell. Note the cylindrical trapping plates are used to confine ions in the z -axis (the magnetic field confines ions in the xy -plane). The middle drawing is a rendering of the PNNL compensated cylindrical ICR trapping cell with segmented capacitive coupled trapping (rendering courtesy of James Ewing, EMSL). The bottom photo is the same PNNL compensated ICR trapping cell rendered above. The photo reveals the cell wiring, insulation, and titanium support structure that holds the cell plates in position. Typically, only nonmagnetic, ultrahigh vacuum compatible components are used in ICR trapping cell construction.

frequency which is proportional to the magnetic field and ion mass to charge ratio, m/z . An additional electric field is required to confine the ions in the z -axis, as the magnetic field confines the ions only in the xy -plane. **Figure 2** illustrates one type of ICR trapping cell geometry and the use of trapping plates to provide the required electric field to trap ions.

Typically, when the ions enter the magnetic field, the resulting ion cyclotron motion is a relatively tight circle. If multiple ions enter the magnetic field, even if the ions have the same mass and charge, the cyclotron motion of the ions will not be correlated; that is, the ions will not be in-phase. Owing to these two factors, the cyclotron frequency of the ions cannot be measured. What is needed is coherent ion motion, that is, in-phase, in a cyclotron orbital with a relatively large radius. Both of these needs

are satisfied by uniformly increasing the ion kinetic energy, a process known as excitation.

As the frequency of ion motion is independent of ion energy, increasing the ion kinetic energy increases the ion cyclotron orbital radius without changing the ion cyclotron frequency (**Figure 1**). In practice, ions are coherently excited by applying an RF electric field, or excitation waveform, between two metal plates (**Figure 2**). If the applied excitation waveform has a constant magnitude, independent of frequency, then the ions will all be excited to the same cyclotron orbital radius. The result of this excitation is that ions with the same m/z circle around as a coherent packet with an increased cyclotron orbital radius.

The ion cyclotron frequency of the excited coherent ion packet is determined by measuring the image current that the packet of ions induces in a metal plate as the ions circle past the plate (**Figure 2**). This image current is recorded as a function of time and is known as the transient or free induction decay (FID). A Fourier-transform of this recorded time series of image current corresponds to the number of ions rotating past the plate as a function of frequency. Simple calibration functions then convert the frequencies to values of m/z .

The resolution of the peaks in FT-ICR mass spectra is directly related to the length of time for which the image current is recorded after ion excitation. The frequency at which the image current must be sampled is determined by the minimum m/z (fastest cyclotron frequency). This is based on known sampling constraints to correctly determine frequency.

Instrumentation

Significant improvements in mass spectrometry instrumentation have occurred since the first commercial FT-ICR MS was introduced by Nicolet Instruments in 1980. An FT-ICR mass spectrometer consists of an intricate and precise collection of components, which will be discussed as in functional subsystems (**Figures 3 and 4**). Improvements in one area can have a cumulative improvement effect or present additional challenges. For example, improvements in magnetic field shielding have allowed for the use of turbomolecular vacuum pumps, whereas overall high magnetic fields have introduced additional challenges in ion transfer. Overall, significant progress continues to be made in every generation of FT-ICR MS platforms. Some improvements have led to new analytical methods that have found broad application in many areas of mass spectrometry. Electron capture dissociation (ECD) developed exclusively in FT-ICR MS led to electron transfer dissociation (ETD), which has been more broadly applied in MS, as just one example.

All FT-ICR mass spectrometers require a homogeneous magnetic field in which to trap ions and generate

the ion cyclotron motion of the ions (**Figure 3**). As many of the fundamental properties of FT-ICR MS directly relate to the magnetic field, improvements in magnetic field homogeneity and increases in magnetic field have had an immediate impact on the capabilities of FT-ICR MS. The majority of high-performance FT-ICR mass spectrometers utilize superconducting magnets to achieve high magnetic fields (some over 15 Tesla) and uniform magnetic fields. As an exception to this trend are the resistive and hybrid resistive/superconducting

Figure 3 A typical commercial 12 Tesla FT-ICR mass spectrometer utilizing active shielding and a refrigerated cryogenic system to reduce the physical and magnetic footprints and the overall system cost (photo courtesy of Bruker Daltonics and used with permission).

magnets at the National High Magnetic Field Laboratory in Florida.

The advances in magnet technology are well demonstrated by the FT-ICR mass spectrometer in **Figure 3**, which has a 12 Tesla magnet with active shielding and cryogen refrigeration systems that significantly reduce the weight and footprint of the magnet. Additionally, the active shielding of the magnetic field reduces the stray magnetic field outside of the magnet housing. This is accomplished by superconducting shield coils at the end of the magnets, which produce magnetic fields to actively counteract the magnetic field of the main superconducting coil.

The majority of the ion path in FT-ICR MS occurs under vacuum conditions (**Figure 4**), and extensive vacuum chambers and differential pumping schemes are required to achieve suitable vacuum pressures. The pressure within a vacuum chamber has a significant impact on the performance of the FT-ICR instrument. For example, the length of time that an excited ion packet will remain coherent is related to the pressure inside the ion-trapping cell. The lower the pressure, the fewer the collisions per unit of time and the longer the useful signal information that can be obtained from the FID.

Vacuum improvements have enabled increases in resolution as transient lengths have increased due to the reduced vacuum chamber pressures. Some care must be given to the design and maintenance of vacuum systems as different regions of the FT-ICR require different vacuum pressures for optimal performance. Commercial FT-ICR MS platforms employ turbomolecular pumps to achieve the required ultrahigh vacuum. Custom FT-ICR systems can be found with diffusion and cryo-pumps.

As FT-ICR MS, like mass spectrometry in general, analyzes charged atoms or molecules, the target analyte

Figure 4 Diagrammed here are some of the major components typically used to generate and transmit ions through the FT-ICR mass spectrometer. Many alternative designs have been implemented with some variations noted in the text. Electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI) are illustrated though many other ionization methods have been successfully implemented with FT-ICR MS. The illustration also demonstrates the use of an ion funnel, though historically many systems have utilized a nozzle skimmer. After the ion funnel, ions travel through a series of differentially pumped regions until they pass through a selection quadrupole and are trapped in an external accumulation multipole. The selection and accumulation regions can be operated in several modes, some of which are further illustrated in **Figure 6**. Ion trajectories during injection to the ICR trapping cell from the external accumulation multipole are typically guided using either RF multipole ion guides or high-voltage ion optics to maximize ion transfer into the ICR trapping cell. After excitation of the trapped ions, the induced image current on the detection plates is first amplified and then passes through a series of signal processing steps, resulting in mass spectra.

Figure 5 The number of publications (left axis, blue curve) and citations (right axis, green curve) per year for publications with Fourier-transform ion cyclotron resonance or FT-ICR MS as the search criteria. Note the rapid rise in publications starting in the early 1990s.

must be ionized and introduced into the mass spectrometer. Many ionization methods have been developed, which tend to perform better for certain analyte classes than for others. Thus, the nature of the analysis dictates the type of ionization method utilized. Ionization methods include electron impact (EI), electrospray ionization (ESI), atmospheric pressure ionization (API), atmospheric pressure chemical ionization (APCI), matrix-assisted laser desorption ionization (MALDI), and others. The development of ionization methods enables the analysis of new classes of analytes or analysis with new MS experimental procedures. For example, the development of ESI and MALDI ionization methods for biomolecules played a significant role in a number of FT-ICR MS publications and citations (**Figure 5**). Note the rapid and sustained publication rate from the early 1990s, which corresponds to the development of ESI and MALDI techniques.

The source region of the FT-ICR mass spectrometer is critical as ions are prepared for injection into the ICR trapping cell (**Figure 4**). This region has the greatest number of differences between FT-ICR MS instruments. Significant improvements and innovations have been made regarding ion selection, reaction, and transmission. For example, ion funnel technologies have been demonstrated to significantly increase the ion current transmitted through the source region (**Figure 4**).

Further, a significant number of FT-ICR mass spectrometers utilize an external trapping multipole to enhance analytical sensitivity. Ions of particular analytical interest can then be selectively accumulated by isolating the ion of interest using a selection quadrupole before the accumulation multipole (**Figure 6**). Note that some implementations combine the selection and accumulation regions into a single device, such as a linear ion trap. An alternative method, DREAMS, selectively ejects the most

Figure 6 The top diagram illustrates ion transmission with no active selection of ions. The most abundant ions, represented by blue and green circles, dominate the ion population of the external accumulation multipole. The middle diagram illustrates the selective accumulation strategy. Here ions of a known m/z (yellow circles) are transmitted through the selection quadrupole, whereas all other ions are ejected. This results in the accumulation of only the selected ions in the external accumulation multipole. Frequently, the selected ions are then subjected to tandem mass spectrometry methods. The bottom diagram illustrates the DREAMS method to extend the dynamic range of an analysis by selectively ejecting only the most abundant ions, which enables the accumulation of lower abundant ions (yellow and brown circles) and even enables the accumulation of ions not observed in nonselective accumulation (red circles).

abundant ions and then accumulates the less abundant ions in the external accumulation multipole, which extends the dynamic range of FT-ICR MS measurements. The DREAMS method is particularly useful in the analysis of samples with a significant range of analyte concentrations, as DREAMS aids in removing highly abundant analytes that can obscure less abundant analytes of interest (**Figure 6**).

An important feature of ion accumulation is the possibility of dynamically modulating the time or flux of ions into the external accumulation multipole as a means to regulate the total number of ions transferred to the analytic ICR trapping cell. This type of regulation can significantly improve the mass measurement accuracy when utilizing a dynamic ion source. For example, such dynamic control of ion population has proven beneficial in liquid chromatography (LC) ESI FT-ICR MS analysis.

Accumulated ions, with or without isolation, can then be fragmented by either collisional activation methods (CAD, CID, etc.) or chemical reaction, like ETD. Also external ion accumulation can be performed during the analysis of ions in the ICR trapping cell, which improves the overall duty cycle. External accumulation multipoles vary from relatively simple quadrupole and hexapole ion traps to sophisticated linear ion traps in so-called hybrid instruments.

Multipole ion guides or high-voltage ion optics are typically used to control the transmission of ions from the external accumulation multipole to the ICR trapping cell due to magnetic fringe fields, which can deflect or even reflect ions (magnetic mirror effect) en route to the ICR trapping cell. This process of ion transmission into the ICR trapping cell is also referred to as ion injection. Improving this ion injection process has also been an active area research. These efforts have focused on improving the overall ion transmission, minimizing the ion kinetic energy, and minimizing spread of ions with differing m/z due to time-of-flight effects between the external accumulation source and the ICR trapping cell, that is, maximizing the m/z range of ions, which can be efficiently trapped in the ICR cell and sampled in a mass spectra.

The heart of FT-ICR MS is the ion-trapping cell (**Figures 2 and 4**). Situated inside the magnet at ultrahigh vacuum, the ICR trapping cell is where the analytical measurements are performed. Although the details of ICR trapping cell design continue to be refined for additional analytical enhancements, the fundamental aspects of ICR trapping cell design have remained unchanged. The consistency of these fundamental aspects of ICR trapping cell design have led some to state that the construction of ICR trapping cells is straightforward and further design is unnecessary. This is an oversimplification that is similar to stating that the fundamental design aspects of making a car are well known and that further design is unneeded.

Just like cars need only four wheels and a motor, the required components of an ICR trapping cell are rather simple. As the magnetic field confines ion motion in two dimensions, all that is needed to confine the ions to a specific region is an additional electric field applied to confine the ions in the remaining dimension, typically referred to as the z -axis with the magnetic field confining ions in the xy -plane. As electric fields for ion trapping are not needed in the xy -plane, a pair of excitation plates for applying the RF excitation waveform to coherently excite the ions and a pair of detection plates to measure the ion cyclotron frequency are placed in the xy -plane. The mass measurement accuracy, sensitivity, and resolution of an ICR trapping cell depend on the quality of design and construction, like the performance of cars depends on these factors.

FT-ICR MS also utilizes a collection of electrical components to acquire mass spectra. Specialized operations generate the appropriate excitation waveforms, which are then amplified to the required amplitude. The image current of the excited ions on the detection plates is amplified, filtered, and then passed to digital-to-analog converters. The acquired data is then typically transferred and stored on a computer where a fast Fourier transform (FFT) is performed followed by application of a calibration function to convert the measured ion cyclotron frequencies to m/z . Technical advancements in the electronic and computer systems have enabled significant reductions in noise and increases in the rate, quality, and total quantity of data collected during FT-ICR mass spectra acquisition.

Applications

FT-ICR MS can be utilized in many applications, particularly those that have stringent requirements for mass measurement accuracy and resolution, the strengths of FT-ICR MS. For example, owing to the resolution and mass measurement accuracy of FT-ICR MS, the elemental composition of small molecules can be determined by a mass measurement alone. For larger molecules, such as proteins, tandem mass spectrometry methods can be utilized to provide additional information to identify and characterize the larger molecules. Indeed, the analysis of complex mixtures, such as top-down proteomics, is greatly aided by capabilities of FT-ICR MS. Bottom-up proteomics strategies, such as the accurate mass and time (AMT) tag approach, also benefit from the use of FT-ICR MS. The analysis of complex polymer distributions is another application in which FT-ICR MS has found application. The analysis of crude oil, perhaps the most complex polymer solution, has been performed utilizing FT-ICR MS in procedures known as petroleomics. Some applications take advantage of the ion trapping combined with the capabilities of FT-ICR MS to perform ion kinetic measurements, ion-ion and ion-neutral reactions, determination of molecular properties, and others.

Fragmentation Reactions of Radical Cations

Organic molecules are usually even-electron species with spin paired valence electrons. The one-electron oxidation of these molecules, which is performed by oxidation with certain transition metal salts, by electrochemical oxidation, by photoinduced single-electron transfer (PET), by ionization using high energy radiation or electron impact, results in odd-electron radical cations. Sometimes these organic radical cations form stable salts which can be isolated; a well-known example is 'Wurster's red', the bromide of the *N,N*-dimethyl-1, 4-diaminobenzene radical cation. Mostly, however, organic radical cations are highly reactive, and the study of radical cations as reactive intermediates of organic reactions is an important and active field of research with respect to both reaction mechanism and synthetic application. In the context of mass spectrometry, the radical cations are usually generated by electron impact ionization (EI) or by photoionization (PI) in the ion source of the mass spectrometer as energetically excited molecular ions with a rather broad range of excess energy. Because of the low pressure (usually $<10^{-6}$ mbar) and the short residence time of the ions within the ion source deactivation of the excited molecular ions by collision does not occur and radiative deactivation is too slow as described by a review by Dunbar (see Further Reading section). Consequently the excess energy of the radical ions created by EI or PI is used for unimolecular chemical reactions, which eventually results in the formation of fragment ions. The surviving molecular ions and the fragment ions formed constitute the mass spectrum of the compound analysed. This illustrates that 'obtaining a mass spectrum' is principally a kinetic experiment, and kinetics laws postulate that in the case of parallel reactions of the same reaction order, which is inherently first order in the case of mass

spectrometric fragmentations, the relative concentrations (intensities I_i) of the individual products match the ratio of the corresponding rate constants k_i (Scheme 1).

Therefore, a detailed interpretation of a mass spectrum both for understanding the reactivity of organic radical cations and for a structure analysis of the compound studied requires the knowledge of the rate constant k_i of the individual fragmentation steps and the dependence of k_i on the structure of the reactants and their excess energy.

The unimolecular fragmentation of excited radical cations in a mass spectrometer refers to the general problem of the reaction kinetics of the decomposition of energized species isolated from their environment. The Rice, Ramsperger, Kassel, Marcus (RRKM) theory, the quasi-equilibrium theory (QET) of Rosenstock and Wahrhaftig, and related 'statistical' theories have been developed to deal with this problem. These theories are discussed in detail in the other articles. Using certain prerequisites they result in eqn [1], showing the dependence of the rate constant k_i on the excess energy E , the number s of vibrational degrees of freedom of the reactant ion, the activation energy E_{i0} and the so-called frequency factor ν_i of fragmentation i .

$$k_i(E) = \nu_i \times \left(\frac{E - E_{i0}}{E} \right)^{s-1} \quad [1]$$

While the oversimplifications used in deriving eqn [1] prevent any genuine calculation of $k_i(E)$ it is useful to demonstrate the factors that influence k_i and its relation to reaction kinetics in a condensed phase at thermal equilibrium. The activation energy E_{i0} has the same

Scheme 1

meaning as in condensed phase kinetics, and in the case of cleavage of only one bond of the reactant radical cation during the fragmentation process, E_{i0} corresponds to the enthalpy of reaction ΔH_r . This approximation is valid because the reverse process of the fragmentation, i.e. bond formation between the ionized fragment (a cation) and the neutral fragment (a radical), requires no or only a very small activation energy (the so-called 'reverse' activation energy). If the excess energy E of the reactant ion (the 'parent ion') is very large ($E \gg E_{i0}$), the rate constant k_f approaches the limiting value of ν . The frequency factor ν reflects the frequency of that vibration of the reactant ion which is transformed into translation along the reaction coordinate of the fragmentation. The frequency factor ν is large if the transition corresponds simply to the elongation of the bond to be broken. The situation is more complicated in the case of a fragmentation by a rearrangement of the reactant radical cation which requires the making of new chemical bonds in a particular conformation as well as bond cleavage. As a consequence of the required conformation of the transition state the frequency factors ν of fragmentations by rearrangement are smaller than those of direct bond cleavages, and a rearrangement can compete successfully for the decomposition of the excited reactant ion only if the activation energy E_0 is small. Generally, a small activation energy is expected for an energetically favourable fragmentation that yields stable ionized and neutral fragments, if any extra reverse activation energy can be neglected.

Applying these general considerations to the fragmentation of organic molecules in a mass spectrometer

Scheme 2

one expects three types of fragmentation reactions. Fragmentations of type I correspond to the direct cleavage of a weak bond of the reactant ion. Since this reaction has a large frequency factor and needs only a small activation energy, the rate constant will be large for any energy regime of the parent ion and the parent ion will always decompose preferably by this pathway. The result is a 'one-peak mass spectrum' that exhibits only the intense signal of the respective fragment ion in addition to a weak peak of the parent ion. Examples of type I fragmentations are found in the mass spectra of many organo-element compounds, which decompose by cleavage of the weak element-carbon bond, and compounds such as *N,N*-dimethyl- β -phenethyl amine (Scheme 2), which fragments into a stable ion $(\text{CH}_3)_2\text{N}^+=\text{CH}_2$ and a stable benzyl radical $\text{C}_6\text{H}_5\text{CH}_2^\bullet$ on electron impact ionization, or β -amino ethanol, which fragments into a stable ion $\text{H}_2\text{N}^+=\text{CH}_2$ and a stable $^\bullet\text{CH}_2\text{OH}$ radical.

A type II fragmentation corresponds to decomposition of the parent ion via a rearrangement into a stable fragment ion and a stable neutral fragment. Because of the stable products the reaction enthalpy of this process is usually small, as in the case of the type I fragmentation. However, the small frequency factor causes a slow rise of the rate constant with the excitation energy of the parent ion. Thus, this rearrangement process is the favoured decomposition pathway for parent ions of low excitation energy. A typical type II fragmentation process is the elimination of H_2O from the molecular ions of *n*-butanol and its higher homologues. Specific studies have shown that this process is mainly a 1,4-elimination and most likely proceeds as a two-step process (Scheme 3) with a slow initial H-atom transfer to the hydroxy group.

A type III fragmentation corresponds to the cleavage of covalent bond compounds, e.g. a C-H or a C-C bond. Since these bonds are rather strong the activation energy of this process (comparable to the reaction enthalpy) is relatively large, but the cleavage is entropically favoured by a large frequency factor. Hence, reactant ions with plenty of excess energy follow this fragmentation pathway. In principle there could be a fourth type of fragmentation, an energetically unfavourable rearrangement process that exhibits a large activation barrier and a small frequency factor. Such a fragmentation will be slow for all energy regimes of the reactant ions and cannot compete

Scheme 3

with the other types of fragmentation. If a process of this type appears in the mass spectrum, there is either no other fragmentation path or a 'hidden' rearrangement of the reactant ion to another isomer precedes the fragmentation. Examples of the first situation are the mass spectra of benzene and polycyclic arenes, which show a distinct signal for the loss of a methyl radical from the parent ion. The only 'simple' fragmentation of these radical ions is the loss of an H atom, which, however, requires about 3–4 eV activation energy because of the strong $C_{\text{arene}}\text{--H}$ bond. Therefore, the deep-seated rearrangement necessary for the elimination of a methyl radical is possible but most molecular ions of the arene do not fragment at all during their residence time within a mass spectrometer. An example of the second situation is the loss of a methyl substituent from the molecular ions of xylene which would require cleavage of a strong $C_{\text{arene}}\text{--C}$ bond and which should not compete effectively with loss of H to generate a stable methyl-benzyl cation (Scheme 4). An investigation of the fragmentation mechanism by Grottemeyer and Grützmacher showed (see the Further Reading section) that a direct loss of the methyl substituent occurs only for highly excited molecular ions, whereas most of the molecular ions rearrange either by H-migration or by a skeletal rearrangement into a methyl cycloheptatriene radical cation before elimination of the methyl group.

The peak pattern of the EI mass spectrum of a standard organic compound arises from competition between type II and type III fragmentations. This will be illustrated below by a few examples to familiarize the reader with the concepts used for the interpretation of the fragmentations of radical ions in a mass spectrometer. However, it has to be remembered that the peak pattern in the mass spectrum of a compound depends very much on the method used for the ionization and on the type of mass spectrometer and scan mode used to acquire the spectrum. The former determines the energy content of the parent ions created in the ion source of the instrument and the latter influences the reaction time allowed for the ions to decompose. If the ionization method chosen supplies only a relatively small amount of excess energy to the molecular ion, the rates of most fragmentations (apart from those of type I) are small and the mass

spectrum will consist mainly of the peak for intact parent ions. At long reaction times ($>10\ \mu\text{s}$) peaks of the product ions of type II fragmentation will appear because of the small activation energies of such processes. 'Soft' ionization methods that produce this category of spectra are field ionization (FI), charge exchange (CE) ionization with a primary ion of low ionization energy (C_6F_6 , CS_2), and multiphoton ionization (MUPI) as described by Grottemeyer and Schlag. In particular, MUPI can be used to steer the ionization into a 'soft' or a 'hard' mode by adjusting the number and energy of the photons absorbed by the molecules of the sample. Ionization of molecules is most often achieved by electron impact (EI) with electrons of 70 eV kinetic energy and is a 'hard' ionization process that produces parent ions having a broad distribution of excess energy up to several eV.

The type of instrument, ion source and scan mode used to obtain the mass spectrum define the reaction time during which the fragment ions that appear in the mass spectrum are generated. A routine sector field mass spectrometer with several kV ion accelerating voltage has a residence time for the ions within the ion source of $<1\ \mu\text{s}$; this time is extended slightly for a quadrupole mass spectrometer using lower accelerating voltages. All ions appearing in the mass spectrum recorded under standard conditions have to be formed within the ion source, and a short residence time is favourable for the observation of fragmentations with a large frequency factor, i.e. type I and type III fragmentations which originate from highly excited parent ions. However, with *tandem-mass spectrometry* the reaction time can be extended by more than an order of magnitude. At a reaction time of $10\ \mu\text{s}$ or longer the highly excited parent ions have decomposed already and only ions with small amounts of excess energy remain. Since the only fragmentation pathways open to these gently excited ions are those with small activation energies, the decomposition of these so-called *metastable ions* occurs predominantly by type I and type II processes. Sometimes this is not very useful for analytical applications of mass spectrometry because the rearrangement and isomerization may obscure the original structure of the molecules analysed, but these low energy processes of the radical cations within a mass spectrometer are more closely related to chemical reactions under thermal conditions and are of eminent importance for an understanding of radical ion chemistry.

Scheme 4

Fragmentation Mechanisms and Fragmentation/Structure Relationship

The fragmentation reactions observed in an EI mass spectrometer are usually discussed with respect to their reaction mechanisms and the effect of structural

parameters of the compound studied on these mechanisms. The types of arguments used in this discussion follow closely the practice used in mechanistic organic chemistry, considering in particular the stability of individual fragmentation products, intermediates and transition states. Some of the more general fragmentation mechanisms observed in the EI mass spectra of organic compounds are discussed in the following examples.

Example 1: Type I Fragmentation and Charge Distribution on the Fragments

For a compound of structure $X-CH_2-CH_2-Y$ where X and Y correspond to functional groups, one expects an easy cleavage of the central C–C bond in the radical cation, generating the fragments $X-CH_2$ and $Y-CH_2$. Only one of these fragments will carry the positive charge while the other one remains as a neutral radical. Stephenson's rule states that in a fragmentation the positive charge appears predominantly with the fragment of lowest ionization energy (IE). This rule is explained easily by the (relative) reaction enthalpy ΔH_r of the competing fragmentations (Scheme 5). Starting from the neutral molecule the ΔH_r for the two fragmentation routes are given in Scheme 5, and since the dissociation energy of the central bond is the same for both processes,

Scheme 5

that with the lowest IE will exhibit the lowest ΔH_r and will be preferred. Examples of this effect are given in Table 1 for neopentyl derivatives $(CH_3)_3C-CR_2-Y$ and β -phenethyl derivatives for the competition between a *t*-butyl or benzyl group and the fragment CH_2-Y .

Example 2: Competing Bond Cleavages and Fragmentation by Rearrangement

A similar example of the effect of the relative reaction enthalpy ΔH_r on the relative abundance of competing fragmentations is obtained by an estimation of ΔH_r for the (hypothetical) C–C and C–O bond cleavages within the molecular ion of *n*-butanol and for the loss of a H_2O molecule. From the data given in Scheme 6 it is seen that C–C bond cleavage next to the α -C atom carrying the OH group (' α -cleavage') is the energetically most favoured but that a fragmentation of the molecular ion by loss of H_2O is even more favoured. The EI mass spectrum of *n*-butanol indeed exhibits large peaks due to α -cleavage by formation of the $^+CH_2OH$ (100% rel. int.) and to loss of H_2O (~50% rel. int.) from the molecular ion as the only abundant primary fragmentation process. However, loss of H_2O requires a rearrangement by hydrogen migration and is hindered by a small frequency factor (type II fragmentation). By investigating specifically isotopically labelled *n*-butanols it was shown that loss of H_2O occurs by a 1,4-elimination and is most likely a two-step process, in which the transfer of the hydrogen atom to the OH group in the first step has an additional activation barrier. Hence α -cleavage (a type III fragmentation) is predominant. However, the long-lived metastable molecular ions of *n*-butanol, which have more time for reactions and which are less excited, decompose only by loss of H_2O . If a similar estimation is made for *n*-butylamine it turns out that elimination of NH_3 is not energetically favoured over the α -cleavage of the molecular ion, resulting in the very stable ion $^+CH_2NH_2$ (m/z 30). This latter process corresponds to a type I fragmentation, and the 70 eV mass spectrum of *n*-butylamine (as most other *n*-alkyl amines) is a 'one-peak' mass spectrum, exhibiting only one intense signal at m/z 30.

Table 1 Ionization energy (IE) and relative intensity (rel. int) in the 70 eV mass spectra of some neopentyl derivatives $(CH_3)_3C-CR_2-Y$ and β -phenethyl derivatives $C_6H_5-CH_2-CH_2-Y$

Compound	IE (eV)	rel. int. (%)	IE (eV)	rel. int. (%)
	Fragment $(CH_3)_3C$		Fragment CH_2-Y	
$(CH_3)_3CCH_2NH_2$	6.7	2	6.1	100
$(CH_3)_3CCH_2OH$	6.7	100	7.56	9
$(CH_3)_3CCH(CH_3)OH$	6.7	100	6.7	93
$(CH_3)_3CC(CH_3)_2OH$	6.7	15	<6.7	100
	Fragment $C_6H_5CH_2$		Fragment CH_2-Y	
$C_6H_5CH_2CH_2NH_2$	7.2	11	6.1	100
$C_6H_5CH_2CH_2OH$	7.2	100	7.56	3

Example 3: The McLafferty Rearrangement

An example related to Example 2 is the fragmentation of the molecular ions of hexan-2-one by α -cleavage at the carbonyl group and by a McLafferty rearrangement, as shown in **Scheme 7**. α -cleavage at a carbonyl group bond gives rise to a stable acetyl cation CH_3CO^+ , m/z 43, and a $\cdot\text{C}_3\text{H}_7$ radical while transfer of an H atom from the γ - CH_2 group to the $\text{C}=\text{O}$ group accompanied by cleavage of the $\text{C}(\alpha)$ - $\text{C}(\beta)$ bond produces the radical cation of the acetone enol and a propene molecule. The latter process exhibits a smaller reaction enthalpy and probably also a smaller activation energy than the α -cleavage, but because of the larger frequency factor ν of this simple bond cleavage the acetyl cation is normally the base peak in the mass spectrum at m/z 43.

The fragmentation of the radical cation of a carbonyl compound by a rearrangement corresponding to H atom transfer from a γ position to the carbonyl group and cleavage of the bond between the atoms at the α and β positions (**Scheme 7**) is known as the *McLafferty* rearrangement and is a general reaction of excited radical cations of aldehydes, ketones, esters and amides. Because of this the McLafferty rearrangement is one of the most widespread and reliable fragmentations for mass spectrometric structure analysis. Its mechanism is related to the well-known Norrish type II photoreaction of carbonyl compounds and has been studied in much detail. Normally the McLafferty rearrangement is a two-step process composed of a 1,4-hydrogen migration to the carbonyl-O atom followed by bond cleavage in the intermediate. This intermediate corresponds to a unique class of radical cations named *distonic ions*, which are characterized by the positive charge and the radical cation residing in separate molecular orbitals, in contrast to 'normal' radical ions (or *molecular ions*) in which the positive charge (the 'electron hole') and the radical electron are located in the same molecular orbital. Distonic ions and their characteristics have been reviewed by Hammerum and by Kenttämä (see the Further Reading section). The properties of distonic ions will be discussed

in more detail in Example 7 below. In the case of the McLafferty rearrangement the distonic intermediate is composed of an oxonium ion (the protonated carbonyl group) and an alkyl radical. The rate of its formation is favoured sterically by the six-membered transition state and depends on the bond energy of the $\text{H}-\text{X}$ bond ($\text{X} = \text{C}, \text{O}, \text{N}, \text{S}$) at the γ position which is cleaved during the process. Any structural feature which lowers the dissociation energy of this bond (for example tertiary $\text{C}-\text{H}$ bond versus primary $\text{C}-\text{H}$ bond) enhances the intensity of the product ion of the McLafferty rearrangement in the mass spectrum. The charge may remain with either of the two fragments of the McLafferty rearrangement according to Stevenson's rule; usually this is the oxygen-containing species. Another interesting detail of the mechanism is the possibility that the two fragments stay bound to each other in the gas phase, forming an intermediate *ion-neutral complex*. (The properties of these intermediate ion-neutral complexes will be discussed in Example 7 and have been reviewed by Morton and others; see the Further Reading section.) During the lifetime of this complex the components may undergo intermolecular reactions, usually H atom transfers that give rise to the 'McLafferty + 1' fragment ion seen in the mass spectra of many esters of long chain alcohols.

Fragmentations related to the McLafferty rearrangement, and often denoted also as a McLafferty rearrangement, are observed in the mass spectra of other organic compounds with a γ -H atom available to a suitable H acceptor group. An important example of this type of fragmentation is radical cations of long-chain alkyl arenes, which contain the ionized arene systems as the H acceptor group (**Scheme 8**). The 1,4-migration of the H atom from the γ position of the sidechain creates a distonic ion composed of a protonated arene (an *arenium ion*) and an alkyl radical. Subsequent bond cleavage within the sidechain gives rise to an alkene fragment and the tautomer of a methyl arene ('isotoluene'), which usually carries the positive charge. An interesting feature of this fragmentation is proton migration within the arenium ion

Scheme 6

Scheme 7

by successive 1,2-shifts (a 'ring walk') which may initiate further reactions.

Example 4: The *Ortho* Effect and Steric Effects on Fragmentations

While the EI mass spectra of the positional isomers of many di- and polysubstituted aromatic compounds are almost identical, the mass spectra of isomers carrying certain substituents in the *ortho* positions are clearly different from the *meta* and *para* isomers. A typical example is the mass spectra of *para*-, *meta*-, and *ortho*-hydroxybenzoic acid. The mass spectrum of the *para* isomer is easily analysed; the main fragment ions arise from a series of simple bond cleavages starting with the loss of an $\cdot\text{OH}$ radical by α -cleavage within the carboxy group (Scheme 9). Analogous reactions are observed in the mass spectrum of the *meta* isomer. In contrast the mass spectrum of the *ortho* isomer (salicylic acid) is dominated by a signal of the fragment ions $[\text{M}-\text{H}_2\text{O}]^{+\cdot}$. An investigation by McLafferty in 1959, of the mechanism of this *ortho* effect showed that the H_2O molecule lost from the molecular ion is generated by a specific transfer of the H atom of the hydroxy group to the neighbouring carboxy group. The loss of H_2O is energetically very favourable, and the frequency factor for the H rearrangement is large because the H donor (the hydroxy group) and the H acceptor (the carboxy group) are fixed in a sterically favourable arrangement of the *ortho* disubstituted benzene ring. Similar intense fragmentations by this *ortho* effect are observed in

Scheme 8

Scheme 9

the mass spectra of many *ortho* substituted arenes, the prerequisites being the presence of an H donor group $\text{H}-\text{Y}$ ($\text{H}-\text{CR}_2$ -, $\text{H}-\text{O}$ -, $\text{H}-\text{NR}$ -, $\text{H}-\text{S}$ -) and the possibility to eliminate a thermodynamically stable molecule $\text{H}-\text{X}$ ($\text{H}-\text{Cl}$, $\text{H}-\text{OH}$, $\text{H}-\text{OR}$, $\text{H}-\text{NH}_2$, etc.) after H transfer to the acceptor group in the *ortho* position. Thus, fragmentation by the *ortho* effect is a very reliable and useful reaction for mass spectrometric structure analysis.

A special aspect of the *ortho* effect, in addition to the 'driving force' of the reaction by elimination of a stable molecule, is the fixed arrangement of the two groups, allowing their intramolecular interaction. This proximity effect or neighbouring group effect, which guarantees a favourable frequency factor ν of the fragmentation by rearrangement, is present in many other semi-rigid organic molecules and can be used to differentiate mass spectrometrically between stereoisomers. An early example of this type of effect is the mass spectra of *cis*- and *trans*-cyclohexanediols and their di-O-methyl ethers, which can be easily distinguished by their EI mass spectra because of the stereospecific fragmentations shown in Scheme 10. However, it should be noted that this type of effect requires that the molecular ions of the stereoisomers do not interconvert before fragmentation.

Example 5: Fragmentations by Intramolecular Substitution

The generation of the principal fragment ions in the EI mass spectrum of benzalacetone is depicted in

Scheme 10

Scheme 11

Scheme 11. These fragment ions can be pictured as arising, at least formally, by a series of simple bond cleavages, with the exception of the formation of the ions $[M-H]^+$. The mass spectra of deuterated derivatives demonstrate that the H atom is lost from the aromatic ring. This is explained by an intramolecular attack of the (nucleophilic) carbonyl group on the ionized benzene ring, eventually giving rise to a very stable benzopyrylium ion via an intermediate related to the σ -complex of aromatic substitution.

This type of fragmentation by an intramolecular substitution has been studied in detail by the author and is a rather common reaction of unsaturated or aromatic radical cations of a suitable structure. The substitution occurs by attack of a nucleophilic group on an ionized $C=C$ double bond or an ionized aromatic ring and is driven by the generation of a stable cyclic fragment ion. By this process a substituent at the attacked position is lost, and the process is particularly abundant in the mass spectra if a weak bond is cleaved, for instance during the loss of a Cl or Br substituent, but methyl or alkyl groups are also easily eliminated.

Interestingly, two definitively different intermediates are generated by the intramolecular substitution of an aromatic ring which exhibit different reactivities depending on whether the positive charge is fixed at the attacking group. In the case of the intermediate created from cinnamic aldehyde, however, both the radical electron and the positive charge are delocalized over the total π -electron system (**Scheme 12**). As a consequence the positive charge may also appear at the (formerly) aromatic ring, giving it the properties of a true σ -complex. In these σ -complexes a proton migrates by successive 1,2-shifts around the ring (*'ring walk'*) before further fragmentation. Consequently, substituents which are good 'mass spectrometric leaving groups' because of a

Scheme 12

small bond energy (such as Cl or Br) are lost not only from the attacked position but also from all other positions after H migration by protolytic bond cleavage (a well-known process of substituted arenes in acidic solutions). The other type of intermediate is represented by the intramolecular substitution within the molecular ion of 2-stilbazole or other related heteroaromatic analogues of stilbene. In this case the positive charge of the intermediate is localized outside of the attacked aromatic ring in a quaternary ammonium ion and only the radical electron is delocalized in the π -electron system. This type of intermediate is therefore a distonic radical cation. The migration of H in radicals by a 1,2-shift is forbidden by the Woodward-Hoffman rules. Hence, from this type of intermediate, substituents (or an H atom) are lost specifically from the attacked position of the aromatic ring.

Example 6: The Toluene-Cycloheptatriene Radical Cation Rearrangement

The examples of fragmentation reactions of radical cations discussed so far correspond either to direct bond cleavages or to bond cleavages preceded by H migration or intramolecular bond formation. These rearrangements do not alter the connectivity of C and other atoms of the original molecules. However, fragmentations of radical cations by 'skeletal rearrangements' are also known. The most familiar example is the interconversion of the radical cations of toluene and cycloheptatriene, which interchanges C atoms within the C skeleton and which gives rise to stable tropylium ions (**Scheme 13**) after H loss.

Scheme 13

The rearrangement of C_7H_8 radical cations has been studied in detail both by experimental methods and by theoretical calculations and the mechanism is well understood. The crucial feature is the initial generation of a distonic ion by a 1,2-H shift from the methyl substituent to the aromatic ring. This is followed by cyclization to a bicyclic norcaradiene-like structure which eventually ring opens to the cycloheptatriene radical cation. This last step exhibits the highest activation barrier of the rearrangement and makes it a high energy process. However, a fragmentation of the toluene radical cation by a direct C–H bond cleavage also needs a large activation energy. Hence, the rearrangement competes successfully with this fragmentation, and a C_7H_8 molecular ion may undergo several reversible toluene–cycloheptatriene rearrangements before the final fragmentation.

It often is assumed that this type of toluene–cycloheptatriene rearrangement applies to other poly-substituted alkylbenzenes, alkylarenes and even alkyl heteroarenes. Indeed, this rearrangement explains the abundant loss of a whole substituent from an arene molecular ion in spite of the normally strong bond to a $C(sp^2)$ atom of the arene, which has to be cleaved to detach the substituent. Rearrangement into a substituted cycloheptatriene radical cation and proton migrations within the ionized seven-membered ring can place any substituent at the $C(sp^3)$ atom of the cycloheptatriene, facilitating the loss of the substituent X from a $>CH-X$ group. Nonetheless, one must realize that the toluene–cycloheptatriene rearrangement is a high energy process of excited ions, and other, less energy demanding, fragmentation mechanisms of polysubstituted arenes into substituted derivatives of the $C_7H_7^+$ ion may override this rearrangement. Thus, the loss of a methyl radical from *t*-butylbenzene radical cations occurs by a direct ‘benzylic’ cleavage, producing the stable cumyl cations, and the loss of a methyl radical from the radical cations of *p*-xylene is preceded by the toluene–cycloheptatriene rearrangement only for highly excited ions that fragment in the ion source of a mass spectrometer, while the only gently excited metastable *p*-xylene radical cations decompose by H transfer to the aromatic ring, a proton ring walk to the position of the second methyl group and protolytic bond cleavage (Scheme 4).

Example 7: Distonic Radical Cations and Intermediate Ion–Neutral Complexes

The examples of mass spectrometric fragmentations of radical cations presented above show that in many cases a process which formally appears to be a simple bond cleavage corresponds to a multistep mechanism and includes several intermediates. The reason for this detour in the fragmentation route is usually the lower activation energy of the multistep process, which converts the original radical cation into an isomer more suitable for fragmentation into thermodynamically stable products. This is especially true if decompositions of metastable ions in a mass spectrometer are investigated, since these ions have long lifetimes and hence do not rely only on fragmentations with a large frequency factor. However, it is always essential that the intermediate ions of the multistep mechanism correspond to energetically favourable structures compared with the original radical cation. Two types of such intermediate ions have gained importance in explaining mass spectrometric fragmentations and will be discussed in this last example: distonic ions and intermediate ion–neutral complexes.

As mentioned before, distonic ions are distinguished from normal molecular ions by the occurrence of the positive charge and the radical cation in separate molecular orbitals. Several examples of intermediate distonic ions have been discussed above, and these distonic ions arise usually by hydrogen migration, for example during the initial step of the McLafferty rearrangement. Other modes for the generation of distonic ions are the ring cleavage of cyclic molecular ions or the addition of a radical cation to a $C=C$ double bond. Depending on the minimum number of atoms between the positive charge and the radical site, α -, β -, γ - or even more distant distonic ions are known. A hydrogen shift within an aliphatic molecular ion to a heteroatom generates distonic ions composed of an onium structure and a radical. The stability of these distonic ions relative to the original molecular ion is important for their role as reaction intermediates, and this can be estimated from the thermochemical cycle (Scheme 14) generated from the energy needed for homolytic cleavage of the C–H bond, the ionization energy of hydrogen, and of the proton affinity at the heteroatom. For a series of isomeric distonic ions with different distances between the positive charge and the radical site the proton affinity of the heteroatom and ionization energy of the H atom are identical. Hence, the essential feature for the relative stability within this series is the dissociation energy of the C–H bond. It can be shown that this is more or less constant, with exception of the smaller C–H bond energy adjacent to the heteroatom. It follows that in this series of isomeric distonic ions the α -distonic ion should always be the most stable. However, the 1,2-H shift necessary to convert the conventional

Scheme 15

molecular ions into distonic isomers by collision with a neutral molecule may occur in different systems.

Because parent ions, fragment ions and the neutral fragments travel through the mass spectrometer at the very high speed resulting from the acceleration by the high electric field of the ion source, the relative velocities of a fragment ion and the corresponding neutral fragment after a fragmentation are usually quite small and the fragmentation products drift only slowly apart. Since ions and neutrals attract each other by ion–dipole and ion–induced-dipole forces, the fragment ion and neutral fragment may be held by electrostatic attraction during the first stages of the dissociation in an ion–neutral complex. This gives the components of the intermediate ion–neutral complex of a mass spectrometric fragmentation a chance to undergo an exothermic bimolecular reaction within the complex. After the dissociation, the result of this reaction mimics the fragmentation mechanism of a rearrangement process. However, since the components within the intermediate ion–neutral complex are more or less free to rotate with respect to each other, this fragmentation route by intermediate ion–neutral complexes avoids the small frequency factor of a rearrangement with a sterically strained transition state. Since the bimolecular reaction within the complex has to be fast to compete with the direct dissociation of the ion–neutral complex, only rather simple reactions (without a large additional activation energy) are observed, i.e. exothermic hydrogen or proton transfer or nucleophilic addition of carbenium ions to electron lone pairs or π -electrons. The first fragmentation of this type was described by Longevialle and Botter (see the Further Reading section) in the mass spectra of certain amino steroids, in which a fragment ion generated at the right-hand side of the steroid molecule transported a proton over a very large intramolecular distance to a functional group at the left-hand side of the steroid. Probably the most ubiquitous fragmentation via intermediate ion–neutral complexes is the loss of alkane molecules that originate from H abstractions by an alkyl radical in an ion–neutral complex generated by a simple C–C bond cleavage of an alkyl chain. Traeger and co-workers (see the Further Reading section) have shown that this fragmentation is especially abundant in the mass spectra of cycloalkanes carrying alkyl sidechains. Indeed, the EI mass spectra of these compounds are distinguished by a series of peaks at even m/z values which arise by this mechanism. Other interesting examples for this fragmentation mechanism are the migration of onium ions (and other stable carbenium ions) over long molecular distances within ion–neutral complexes before the terminating ion–molecule reaction. This corresponds to a reactive interaction between two functional groups which are far apart in the original molecule. Thus, this type of fragmentation provides an explanation for a formal

rearrangement by migration of functional groups within the original molecular ion.

Secondary Fragmentation

As discussed in the introduction and shown in **Scheme 1**, the fragmentations of organic molecular ions, which are induced by electron impact in a mass spectrometer and which give rise to the peak pattern of the EI mass spectrum, correspond to a kinetic scheme of parallel and consecutive unimolecular reactions. Any fragment ion that still contains sufficient energy for further fragmentation will do so, and these fragmentations correspond to the reactions of an isolated and energetically excited species described by QET or RRKM theory. However, the radical cations (molecular ions) generated by EI from the neutral molecules may decompose either by elimination of small neutral molecules (loss of H_2O , see Example 2; loss of alkene, see Example 3) or by loss of radicals. In the former case the newly generated secondary fragment ions correspond to radical cations, while in the latter case the fragmentations give rise to secondary even-electron cations. The different electronic nature of the fragment ions has an effect on the preferred pathways for further fragmentations.

The types of fragmentation reactions observed for secondary radical ions are more or less those discussed in the previous section. Thus, the fragmentations of the $[\text{M}^{\bullet+}-\text{H}_2\text{O}]$ fragment ions in the mass spectra of aliphatic alcohols concur with those of the radical cations of the corresponding alkenes (or alkylcyclobutanes), and because of these further fragmentations of secondary fragment ions the mass spectra of long chain alcohols and alkenes are very similar. In comparing the fragmentations of secondary radical cations with radical cations produced directly by EI from stable neutral molecules one has to account for the different excess energy present in radical cations originating from EI and from fragmentation, and, more importantly, for the possibility that fragment ions may correspond to distonic isomers or tautomers of the molecular ions. Thus, the secondary $\text{C}_3\text{H}_6\text{O}^{\bullet+}$ radical cations created by the McLafferty rearrangement of the molecular ions of hexan-2-one (**Scheme 7**) correspond to the ionized enols of acetone and not acetone radical cations, and further fragmentation may require ‘re-ketonization’. Similarly, elimination of an alkene fragment from the molecular ions of alkylbenzenes gives rise primarily to an isotoluene radical cation (**Scheme 8**) which differs in reactivity from the toluene molecular ion. In most cases these differences alter the details of the fragmentation mechanisms, but not the principal routes of a further fragmentation.

Secondary fragment ions which are even-electron cations prefer the elimination of neutral molecules in their further decompositions. This has inspired the formulation of the so-called 'odd-even-electron' rule which states that odd-electron radical cations may yield either odd-electron or even-electron secondary ions on decomposition while even-electron cations produce only smaller even-electron cations as products. However, many exceptions to this rule are known, in particular for the mass spectra of large polyalkylated arenes and of organo-element compounds. In individual cases it is clearly the stability of the product ions which directs further fragmentations. Nevertheless, the rule can still be used as a first guide for the interpretation of mass spectra of organic compounds. The elimination of a

small molecule from an even-electron cation is achieved by a shift of an electron pair only or by hydrogen migration. A typical example for the former mechanism is the fragmentation cascade observed for the $[M-CH_3]^+$ ion in the mass spectrum of benzalacetone while the latter fragmentation is typical of alkene eliminations from the onium ions produced by α -cleavage (**Scheme 17**).

Even-electron cations are known to rearrange easily by 'electron-sextet rearrangements' of the Wagner-Meerwein type. In particular, alkyl cations and other hydrocarbon cations rearrange easily by this mechanism. Thus, 1,2-hydrogen shifts and 1,2-alkyl shifts in an alkyl cation compete successfully with a direct fragmentation by alkene loss as depicted in **Scheme 18**. The formation of an unstable primary alkyl cation by direct bond

Alkene elimination from onium ions:

Scheme 17

Scheme 18

cleavage within a molecular ion is very likely associated with a concerted 1,2-H shift to create a more stable secondary fragment ion. As a consequence of these rearrangements the abundant C_3H_7^+ and C_4H_9^+ ions observed in the mass spectra of *n*-alkanes at m/z 43 and m/z 57 correspond to stable isopropyl cations and *t*-butyl cations.

Introduction

A major advantage proposed for the application of Raman spectroscopy to many problems is the minimal sample preparation required for presentation of the specimen to the spectrometer. Unlike most other analytical techniques, no chemical or mechanical pretreatment is necessary; of particular relevance to biological and biomedical studies is the ability to obtain Raman spectra from specimens which are in their state of natural hydration without further desiccation. The weak Raman scattering of hydroxyl groups and silica means that water and glass will not strongly affect the observation of Raman spectra. In other cases, specimens which have been prepared for optical microscopy and protected using standard glass cuvettes or slide cover-slips can also be studied using a Raman microscope without any changes being effected.

The swamping of weaker Raman spectra by strong fluorescence emission in the visible region of the electromagnetic spectrum is an occupational hazard of Raman spectroscopy using laser excitation, particularly in the blue and green regions (400–520 nm). This arises from the high latent energy of excitation at these wavelengths. In some cases sample fluorescence arises from impurities in the specimen, and in these cases sample treatment may be indicated. This may be a trivial or difficult task, depending on the particular specimen being studied. For example, the swabbing of biological tissue, which is common practice to remove surface contaminants, is neither effective nor admissible when archaeological bio-materials are being studied, which may have involved the absorption and concentration of fluorescent materials over a long period of time.

It has often been reported that prolonged exposure of a specimen to a laser beam will produce a Raman spectrum with enhanced signal-to-noise (the little-understood physical phenomenon of 'fluorescence burnout' which is illustrated in **Figure 1**); by this means, good quality Raman spectra can be recorded in the presence of fluorescent material. However, the removal of the fluorescence emission is only temporary and the method is not always appropriate. Some biomaterials, such as skin and wool, exhibit strong fluorescence in the blue region of the spectrum and their Raman spectra generally cannot be recorded using laser radiation around 480 nm.

The choice of exciting line wavelength is therefore of critical importance for the observation of Raman spectra of biomaterials without attendant fluorescence emission. A particular advantage of the move towards red excitation (600–800 nm) and particularly the near-infrared (1064 nm) is the minimization of fluorescence from biological tissues and organs, such as skin, because of lower excitation energies. Other methods of combatting fluorescence have involved the use of pulsed laser excitation and d.c.-chopping or synchronization of the scattered radiation to electronically filter out the background emission.

When coupled to a microscope a Raman instrument with a high spatial resolution (approximately 5 μm) is then available which can produce spectra that are largely fluorescent-free. The Raman microscope exhibits a high signal-to-noise ratio and is ideal for the characterization of weak scattering samples and analysis of specific regions within a sample.

Another attachment that can be coupled to a Raman spectrometer is a remote probe. This consists of a fibre optic cable that passes the laser beam to a sample outside the conventional sampling chamber. This can be of use in many different applications, the most obvious of which is where the sample is too large or complex to fit into the instrument. *In vivo* biological studies utilize a fibre optic probe for the investigation of human tissue. Industrial process monitoring uses a Raman spectroscopic probe for online quality control during manufacture.

The linear dependence between intensity of scattering and species concentration means Raman spectroscopy is not considered to be a sensitive technique for trace quantities of material, unless these are localized, can be identified microscopically and have a large molecular scattering cross-section factor. However, the linearity of dependence between concentration and observed band intensities can be used to good effect in quantitative Raman spectroscopy, especially for solution equilibria, for which important physicochemical data can be obtained, such as rate constants, equilibrium constants and enthalpies of chemical bond formation or breakage. Hence, whereas in absorption spectrometry weak bands can be enhanced using larger pathlengths, this is not practicable in Raman spectroscopy.

The effect of the input of high energy visible laser radiation into samples with consequent possible increased fluorescence emission may also be marked in local sample heating. This is particularly important for valuable samples

Figure 1 Dissipation of fluorescence in wool on extended exposure to laser irradiation. (a) 0, (b) 30 and (c) 210 s (633 nm, 5 s acquisition time).

that must not suffer damage during analysis; also, coloured materials may absorb the laser radiation particularly effectively and literally burn in the process. For this reason, high laser powers focused onto stable mineral or geological materials are not acceptable for sensitive biomaterials and an experienced Raman spectroscopist would always attempt to use low laser powers initially on samples whose reaction to laser radiation is not known. Even when sample degradation or damage does not occur through laser absorption, for this reason, special devices based on a spinning sample illumination system exist where the species is permitted to have only low residence times in the laser focus, so reducing the localized heating.

With 1064 nm infrared excitation, generally used in FT-Raman studies, the effect of sample heating is noted first in emission at higher wavenumber shifts ($>2000\text{ cm}^{-1}$), but the problem is exacerbated when the sample itself is being thermally investigated. For this reason, the 'background' emission of infrared radiation at higher wavenumbers with 1064 nm excitation varies with sample temperature until near 200°C , whereupon it becomes effectively unworkable, e.g. the Raman spectrum of S_8 at elevated temperatures.

Biological Materials

Fluorescence and the inherent weakness of the Raman effect seriously hampered the use of Raman spectroscopy for the routine analysis and investigation of biological samples. Until the commercial development of the FT-Raman technique in 1986 some researchers went to quite extreme lengths to overcome these problems. This is well demonstrated by workers who found it necessary to 'burn out' fluorescence in wool for up to 20 hours before being able to acquire an acceptable Raman spectrum.

The keratins are a specialized group of structural fibrous proteins that are characterized by their high cystine content and can be classified according to the amount of sulfur present in the protein. Structures such as wool, hair, hooves, horns, claws, beaks and feathers are classified as 'hard' keratins because the sulfur concentration in these proteins is greater than 3%. Keratin proteins containing less than 3% sulfur, such as the stratum corneum (the outermost layer of skin), are classified as 'soft' keratins. Although these keratin proteins

have a similar molecular composition, major spectral differences have been observed in: the intensities of the C–S and S–S stretching vibrations; the conformation of the disulfide bond; and the position, line shape and bandwidth of vibrations associated with the protein secondary structure.

Figure 2 shows the FT-Raman spectra of wool (Figure 2a) and hydrated stratum corneum (Figure 2b) over the wavenumber regions 2600–3600 cm^{-1} and 400–1800 cm^{-1} . The presence of water, at ca. 3200 cm^{-1} near the $\nu(\text{CH})$ stretching region (2800–3100 cm^{-1}) can be clearly seen; the characteristic amide I, $\nu(\text{CONH})$, $\delta(\text{NH}_2)$ and $\delta(\text{CH}_2)$ modes are seen in the region 1200–1700 cm^{-1} . Lipid modes are near 1000–1200 cm^{-1} and the prominent $\nu(\text{SS})$ band in wool near 500 cm^{-1} is also noteworthy.

Raman spectroscopy has been used for the characterization of stratum corneum, epidermal membrane and dermal tissue. Of current interest is the administration of therapeutic agents across the skin barrier (transdermal drug delivery); however, there are a number of difficulties which involve the supply, storage and use of biohazardous human material.

Medical/Pharmaceutical

The use of Raman spectroscopy in medical diagnostics is an ever-expanding field of application. Again, features such as the nondestructive and noninvasive nature of the technique mean that the technique is well suited to this type of application. Raman spectra have often been masked by fluorescence from some of the naturally occurring constituents of animal tissues. Raman spectra of cells and tissues are usually excited in the near infrared with radiation at 780, 830 or 1064 nm as the probability of exciting fluorescence is reduced at these longer wavelengths.

Raman spectroscopy has been used for the compositional analysis of gallstones and kidney stones; the distribution of the mineral and organic components of a human tooth have been mapped by FT-Raman microspectroscopy; and the characterization of normal and pathological tissues including breast, liver, colon and brain. Furthermore, analysis can be performed *in vitro*, on biopsy samples, or *in vivo* whereby spectra are recorded using a fibre optic cable. Examination of complex Raman spectra that contain a large number of bands as in biological tissues can be somewhat subjective, and it is often

Figure 2 FT-Raman spectra of (a) untreated Merino wool, and (b) hydrated stratum corneum.

difficult to detect subtle changes or differentiate between similar spectra. To overcome this problem it is necessary to automate the interpretation of spectra by developing a non-subjective technique for analysis, such as a neural network which has been successfully used to differentiate between Raman spectra of basal cell carcinoma and healthy skin.

Interactions between hydroxyapatite crystallites, inorganic ions, cellular components and the organic matrix in living tissues form part of the complex process known as biomineralization. An example of biomineralization is the production of calcified tissues such as bone and teeth. The Raman spectrum of bone is dominated by a very intense vibration at 960 cm^{-1} , which is attributed to the phosphate stretch of the hydroxyapatite component.

Bone implants are commonly made of metal coated in a similar material to bone, i.e. synthetic hydroxyapatite, to improve the biocompatibility and to aid bonding between the natural bone and the implant. Raman studies of bone implants utilize the spectral difference between bone and that of synthetic hydroxyapatite. The synthetic material lacks many of the characteristic Raman vibrations of bone and those of phosphate have significantly reduced bandwidths. Thus, it is possible to study the interface between the implant and the recipient's bone. Biomineralization of implants coated with materials other than hydroxyapatite can be followed by monitoring the intensity of the phosphate vibration related to those produced by the coating material.

Art and Archaeology

The identification of materials that make up an object is important to art historians and archaeologists for a variety of reasons. Information can be provided on trade routes that existed at the time, the development of artistic styles and techniques and the understanding of chemical technology. This information may help to authenticate and date an object, and aid in the process of restoration and conservation. Identification of the products of degradation will help in devising a regime for treatment to arrest or reverse the deterioration, thus aiding the conservator in the preservation of the object. In many cases previous conservation treatments are a problem as the materials used break down and damage the object. Often treatment records have not been kept, or are lost, and analysis is required to identify the materials previously employed so they can be successfully removed.

Some problems have been found in analysing archaeological materials from certain burial environments where absorption of coloured and/or fluorescent impurities has taken place. Special care has also to be taken when handling rare or very fragile samples. Often very

low laser powers are necessary in order to prevent thermal damage from occurring. These problems are being overcome and Raman spectroscopy is now being applied to the identification of a diverse range of material types including pigments, resins, waxes, gums, ivory and ancient skin.

Pigments

Pigments can be found on a wide range of objects such as paintings, frescoes, manuscripts and china. Often only a very small section of the pigment will remain perhaps only several grains. It is important to be able to identify the pigment (often *in situ*) without harming the object in anyway. Raman microscopy has been found to be one of the best techniques for identifying pigments. It is sufficiently sensitive to analyse pigment grains, generally does not suffer from interference (from surrounding media such as binders) and most importantly it is nondestructive. It is also possible to identify components in a pigment mixture, as the spatial resolution of the technique is about $\leq 2\text{--}10\text{ }\mu\text{m}$. A wide range of pigments have been identified using Raman spectroscopy; for example, it is possible to differentiate between the red pigments: red lead, red ochre and vermilion used in antiquity and to determine the mixture composition quantitatively and nondestructively (see **Figures 3b**, **Figure 3c** and **Figure 3e**).

Pigments used in the wall paintings in Winchester Cathedral and Sherborne Abbey have been analysed using FT-Raman spectroscopy. Wall paintings from circa 1175–1185 are found in the Holy Sepulchre Chapel, North Transept of Winchester Cathedral. They illustrate several scenes around the Crucifixion and are amongst the most important paintings of their period in the UK. Those found at the Chapter House at Sherborne Abbey are much more fragmentary and date to the late 12th/early 13th century. The Raman spectra shown in **Figure 3** demonstrate that the pigment from Sherborne Abbey (**Figure 3d**) is pure vermilion (**Figure 3c**) whereas that from Winchester Cathedral (**Figure 3a**) is a mixture of red ochre (**Figure 3b**) and vermilion (**Figure 3c**). Adulteration of pigments was practised for economic reasons even though it was recognized that the resulting pigment mixture stability could be adversely affected. Also, variation in pigment composition over a painting could indicate to a conservator that some more recent renovation has been under-taken.

Analysis of frescoes at the palazzo Farnese, a mansion at Caprarola, Italy, helped to characterize chemically the biodeterioration that had occurred. A circular courtyard at the mansion has inner walls at ground and first floor levels bearing frescoes painted by Zuccari in the 1560s. In recent years serious biodeterioration through lichen invasion has affected the frescoes. *D. massiliensis* forma *sorediata*, which produces oxalate encrustations which are

Figure 3 FT-Raman spectra of (a) pigment from wall painting in Winchester Cathedral (baseline corrected) (b) red ochre, (c) vermilion, (d) pigment from wall painting in Sherborne Abbey, and (e) red lead pigment.

almost 2 mm thick in some places, is responsible for the disfigurement and the chemicals involved in this process have been identified by Raman spectroscopy.

Archaeological resins

Raman spectroscopy can be used to identify different natural resins. By comparing spectra from ancient resins with a database of modern materials it is sometimes possible to identify the source of the ancient sample. An example of this use is the identification of the different forms of the resin 'dragon's blood'. Since ancient times this resin has been used for a diversity of medical and artistic purposes. This rich red resin has been used to make varnishes for a variety of objects including reputedly 16–18th century Italian violins such as those made by Stradivarius. Many cultures have at least one indigenous natural resin which they call 'dragon's blood' but the botanical sources are not necessarily the same. Today, the primary commercial supply of dragon's blood is the resin from the fruit of the Southeast Asian rattan, or cane-palm, *Daemonorops draco* (*Palmae*). In Western antiquity, in the Roman Empire, one of the main sources was *Dracaena cinnabari* L., which was once prevalent around the Mediterranean coast, but now endemically localized to Socotra Island, off the Horn of Africa. **Figure 4** presents the FT-Raman spectra of these two resins. Clearly the spectra are very different and provide a means of identification of a botanical source of 'dragon's blood' resin. Elsewhere, other trees have been tapped for their 'dragon's blood' such as *Eucalyptus resinifera* (actually

a gum) in Australia. The FT-Raman technique is capable of distinguishing between fresh resins from these three sources mentioned. Identification of the resin can play a deciding role in the cleaning or stabilization of an object coated in resin and with the provenancing of the artefact.

Forensic Science

The field of forensic science, scientific analysis used within the legal system, is very wide-ranging; narcotics and explosives are amongst the areas of analysis covered. Many different techniques are used within the field to identify samples found at a crime scene or seized by police. Techniques used must fulfil certain requirements: sensitive enough to deal with often very small or trace samples, provide clear, characteristic results which easily distinguish different materials and minimal sample size and preparation. The latter point is one which Raman spectroscopy can easily fulfil, as the technique is both nondestructive and noninvasive. No sampling is required, which means that further analysis is possible should it be necessary, for example in the case of an appeal. Raman spectroscopy fulfils the other requirements as it is both sensitive and provides characteristic spectra for different substances.

Raman spectroscopy has been applied to a range of different materials of interest to the forensic scientist. A wide range of narcotics can be identified including heroin, cocaine and amphetamines. The wavelength of excitation has to be varied, as some samples are highly

Figure 4 FT-Raman spectra of (a) *Daemonorops draco* (Palmae), and (b) *Dracaena cinnabari*.

fluorescent under certain conditions. For example, heroin fluoresces when excited at 633 nm but a clear, characteristic spectrum can be obtained with resonance Raman using 244 nm excitation. Fluorescence can also be a problem if a narcotic has been 'cut' (mixed) with a fluorescent material. The spectra of these 'street' drugs require baseline correction in order to be successfully compared with a database of 'pure' standards or again a lower wavenumber excitation can be employed. Narcotics often enter the laboratory in a crime scene bag and may also still be in their original packaging – often wrapped in plastic. It has been found that it is possible to take a Raman spectrum of the sample through the packaging (including black plastic), subtracting the spectrum of the packaging to get a spectrum of the sample alone. This is very useful in forensic science as this minimizes any contamination that could occur to the sample during preparation for analysis. Along with the lack of any sample preparation required and with provision of a suitable database, a computerized analytical instrument means that relatively unskilled users could potentially use Raman spectroscopy to analyse any seizure more quickly.

Raman spectroscopy has also been applied to the identification of different explosives. Most explosives, both nitro-containing (i.e. 2,4,6-trinitrotoluene (TNT)) and non-nitro-containing (i.e. TATP), produce high quality, low fluorescence Raman spectra. Some plastic explosives (i.e. Semtex) have some fluorescence originating from the binder materials but this can be overcome by use of anti-Stokes bands and Boltzmann correction of the data.

Raman microscopy has been used for the analysis of gunshot residues. Chemical analysis of the materials that leave the barrel of a gun on firing can give information about the gun, the ammunition, the shooting distance and direction. All of this information is important for investigators of any shooting incident. The residues that leave a gun on firing are deposited on the victim, user, weapon and within the immediate vicinity. Gunshot residues are composed of the metallic components of the bullet, partly burnt propellant particles and particles of elements originating from the primer, the bullet, the propellant and the propellant additives. Raman microscopy has illustrated that different metal anions contained in gunshot residue such as carbon, barium

Figure 5 FT-Raman spectra of (a) African elephant ivory, (b) micarta, (c) an imitation ivory and (d) calcite.

carbonate, lead sulfate, lead oxide and mixtures of these compounds are easily identified.

Real or Fake?

An area that combines the interests of historians and forensic scientists is whether an object has been constructed from the material from which it is purported to have been made. Rare or valued materials are often replaced by cheaper, more easily available imitations, some of which are of such good quality that they deceive even expert examination. Examples of these materials are ivory and amber, both having been simulated using a wide range of materials, including modern polymers. In some instances great effort is given by the forger to copy the weight and texture of the original material. Ivory is much heavier than many modern plastics so fillers such as calcite (calcium carbonate) may be added so that the weight then more closely matches that of ivory. On highly carved objects it can be very difficult to identify the material as genuine ivory, for example, or an imitation. The 'hot pin' test has been used to identify modern plastics, over ivory. Plastic materials will tend to melt or burn when a hot pin is applied but it will have no effect on genuine ivory.

This rather crude method has one quite obvious drawback in that a plastic object will be marked. Even though the item is not made of ivory it may still be of some value, which would be affected by any marking. FT-Raman spectroscopy provides a good alternative; a result can be obtained almost as quickly and the object is not damaged. The spectra of ivory and amber are clearly different to polymeric imitations, so a definitive identification can be given where previously it has proved difficult, or impossible, to do so visually. This is illustrated in **Figure 5** which presents the FT-Raman spectra of African elephant tusk, micarta (phenolic thermoset resin), an imitation ivory and calcite. It can be seen that the spectrum of the imitation ivory contains vibrational features which are characteristic of polymer mixtures, in this case polystyrene and polymethylacrylate. The spectrum of micarta indicates that it probably contains either polyethylene or polybutylene terephthalate.

Gemmology

Analytical techniques commonly used in gemmology include X-ray and neutron diffraction, scanning electron

microscopy and, more recently, FT-Raman microscopy. Traditional identification is based on the gems' unique physical, chemical and optical properties. These include specific gravity, cleavage, hardness, toughness, fracture, refraction, transparency, lustre and sheen. However, some gemstones have similar properties; for example, taaffeite ($\text{BeMgAl}_4\text{O}_8$) and musgravite ($\text{Mg}_2\text{Al}_6\text{BeO}_{12}$) have essentially identical gemmological properties. The advantage of utilizing Raman spectroscopy for analysis lies in the non-destructive nature of the technique, rapid identification and the ability to analyse both carved and rough surfaces.

Other applications include the detection of synthetics and imitations, the detection of composite or assembled stones and the investigation of inclusions to assist in the identification of the origin of the gemstone. In order to hide surface cracks, improve colour or provide protection for soft stones, gemstones may undergo certain enhancement treatments. For example, they may be treated with oil, artificial resins or waxes to fill any fissures or fractures, thus improving their clarity. These foreign substances produce distinctive Raman spectra from which their presence may be identified.

Polymers and Plastics

Characterization of polymers and their reaction processes can be carried out using Raman spectroscopy. Both qualitative and quantitative information can be provided about stereoregularity, chemical nature, orientation, conformation and three-dimensional state of order in a polymer. The polymerization process may also be monitored, allowing the effect of different parameters on the course of the reaction to be analysed. Many different polymers and polymer reactions have been studied using Raman spectroscopy in recent years, for example, epoxysilanes that are used to obtain hybrid polymers via a sol-gel process.

Process control and remote Raman sensing are now possible through the application of fibre optics. Remote measurements can now be taken directly in the reaction vessel. The real-time monitoring of chemical reactions can aid in the streamlining of the process and thus produce cost savings. The minimal fluorescence produced using near-infrared excitation means that FT-Raman spectroscopy is becoming widely accepted as an industrial tool. An example is the analysis of waterborne polymer emulsions, i.e. styrene/butadiene copolymers, which are used as binders in coated paper and carpet manufacture. Raman spectroscopy is useful in this case due to little interference being caused by the aqueous phase or the scattering effects from the emulsion particles, which can be a problem with other spectroscopic techniques.

Assessment of the mechanical properties and engineering applications of polymers is made by consideration of orientation, conformation and three-dimensional state of order of the polymer during the deformation processes. FT-Raman spectroscopy is also applied to the analysis of transient structural changes induced by polymer deformation. For a clear understanding of a deformation mechanism, characterization of structural changes is required online. Studies have been performed on a wide variety of polymers during elongation and recovery, to monitor phase transitions and alterations in crystallinity and anisotropy. Particularly useful for this purpose has been the simultaneous analysis of mechanical and spectroscopic properties, called rheoptical measurements.

Inorganic/Organometallic Materials

A typical FT-Raman spectrum covers the wavenumber range $100\text{--}3500\text{ cm}^{-1}$, which encompasses the skeletal vibrational modes of organic molecules normally occurring in the functionality region ($1000\text{--}2000\text{ cm}^{-1}$) and the bonds between heavy metals and carbon, oxygen and sulfur which all occur below 500 cm^{-1} . This ability to record the spectra of 'inorganic' and 'organic' components within a sample is a valuable attribute of Raman spectroscopy. For example, the Raman spectrum of mercury (II) sulfide (commonly known as vermillion), shown in **Figure 3c**, exhibits a strong Raman band due to $\nu(\text{HgS})$ at 257 cm^{-1} which is not normally seen in infrared spectroscopy unless special instrumentation is used.

The ability of Raman spectroscopy to detect co-ordinate bands in inorganic and organometallic compounds lends itself particularly well to the observation of metal-metal, metal-halogen and metal-phosphorus clusters such as $\text{Ag}_4\text{I}_4(\text{PMe}_3)_4$, metal-oxygen bonds in corrosion studies involving zirconium(IV) oxide and iron(III) oxide in nuclear fuel claddings and steels, and metal-carbon bonds in organometallic compounds used in catalysis.

Studies of metal ion coordination with anion ligands in mixed organic/aqueous solvent systems have provided novel information about the metal ion coordination numbers and mechanism of crystallization processes from Raman spectroscopy. Also, thermodynamic parameters such as enthalpy of band formation or breakage have been evaluated from Raman spectra of solution studied over a range of temperatures.

Geological Materials/Solid States

Access to the low-wavenumber regions of the vibrational Raman spectra of minerals and solids of geological

relevance has yielded information on crystal lattice symmetries and on the effect of ionic impurities. Databases of geological materials now rival those of organic compounds and affiliations to solid-state physics, crystal engineering and to substrate characterization for thin-film devices are numerous.

Some of the most recent affiliations in this area include the analysis of extraterrestrial material in the form of Martian meteorites (Shergotty–Nakhla–Chassigny classification) and in the characterization of simulated soils for planetary exploration.

BOLD	blood oxygenation level-dependent
fMRI	functional magnetic resonance imaging
PET	positron emission tomography

A core goal of neuroscience is to elucidate the neural mechanisms that underlie important aspects of human cognition. Key areas of research include understanding how people perceive the world, how they remember important events, and even how they make decisions that can shape their future. In recent years, the neuroscientist's arsenal has gained an important new tool for addressing these topics: functional magnetic resonance imaging (fMRI). Even though only two decades have passed since the first coarse fMRI experiments, the field has already developed such that more than 1500 studies using fMRI are published annually. Why has fMRI grown so rapidly? Although its predecessor positron emission tomography (PET) requires injection of some radioactively labeled metabolite, fMRI measures naturally occurring blood oxygenation level-dependent (BOLD) contrast. Data can be acquired using standard clinical MRI scanners (Figure 1), of which there are more than 10 000 in North America alone. The broad availability of these machines has made fMRI accessible to thousands of researchers, many originally from fields outside of neuroscience. The measurements obtained using fMRI allow study of many cognitive processes. The spatial resolution of fMRI is on the order of a several millimeters, allowing researchers to identify areas of distinct function. The temporal resolution of fMRI is on the order of several seconds which is much slower than measurements of brain electrophysiology, but fast enough for many research questions. While a complete discussion of fMRI is beyond this article's scope, it provides a broad overview to the basic principles of fMRI, from physics and neurophysiology to experimental design and analysis.

Physical Principles of MRI

All MRI scanning techniques, including fMRI, rely on three core concepts (Figure 2): magnetization, resonance, and image formation. First, a large superconducting solenoid coil generates a very strong magnetic field that induces magnetization in tissue protons. Second, an excitation coil sends pulses of radiofrequency energy into

Figure 1 A modern MRI scanner. The same scanner can collect clinical MRI images and fMRI data as well as collect other sorts of MRI data, like spectroscopic measurements. The subject lies down on the table in the foreground and places his or her head inside the volume coil at the center of the image. Surrounding the central bore of the scanner are the coils that generate the strong static magnetic field and weaker gradient magnetic fields; these two sets of coils are hidden behind the plastic cowlings. Reproduced from Huettel SA, Song AW, and McCarthy G (2004) *Functional Magnetic Resonance Imaging*. Sunderland, MA: Sinauer.

the tissue; by calibrating this coil to a particular resonant frequency of the magnetized protons, that energy will be absorbed by the protons and later re-emitted as the MR signal. Third, a set of spatially organized gradient coils are used to strengthen or weaken the magnetic field very slightly across space, which provides spatial variation in the MR signal. Depending on the particular pattern of radio-frequency pulses and magnetic gradients, images can be acquired that are sensitive to brain structure or function.

Most structural MRI scans, and all fMRI experiments, create images sensitive to properties of the nuclei of the hydrogen atoms (protons), typically within water molecules. The proton has a quantum property called 'spin,' and so long as no strong magnetic field is present, the spin axes of protons will orient in random directions, leading to no net magnetization. However, the strong field of the MRI scanner exerts a force upon the protons to create a net magnetization that, in conjunction with their angular momentum, induces a gyroscopic motion known as precession. The precession or Larmor frequency is proportional to the strength of the static magnetic field; for protons, this is approximately

Figure 2 A schematic overview of the hardware required for fMRI research. The scanner is controlled by electronics that generate the pulse sequences used in fMRI experiments. Key components include amplifiers that create spatial gradients in three directions and a radiofrequency amplifier that controls the output of the head coil. The MR signal is measured in that same head coil and then transmitted back to the scanner console room for subsequent reconstruction. For fMRI experiments, additional systems are necessary for displaying stimuli, recording behavior, and analyzing the data. Reproduced from Huettel SA, Song AW, and McCarthy G (2009) *Functional Magnetic Resonance Imaging*, 2nd edn. Sunderland, MA: Sinauer.

42.58 MHz T^{-1} . Each proton's axis of precession will be aligned either parallel to the static magnetic field, which represents a low-energy state, or antiparallel to the static magnetic field, which represents a high-energy state. At room temperature, there are slightly more protons in the low-energy state, which results in a net magnetization whose major component is parallel to the main magnetic field (i.e., in the longitudinal direction). Like its constituent protons, the net magnetization also precesses around that longitudinal axis at the Larmor frequency (i.e., changing within the transverse plane) (Figure 3).

For protons to change from the low-energy state to the high-energy state, they must absorb electromagnetic energy (i.e., photons). To effectively deliver that energy, the MRI scanner applies an energy pulse whose frequency

matches the Larmor frequency of the targeted protons. This process, known as excitation (Figure 4(a) and 4(b)), is analogous to pushing a child on a backyard swing set. Delivering one very large burst of energy (i.e., a single strong push) will lead to only minimal movement, whereas continual application of energy at the resonant frequency of that swing set will (i.e., repeated small and well-timed pushes) cause a dramatic increase in the child's velocity. Similarly, MRI scanners use specialized coils to transmit electromagnetic energy at the resonant frequency of the hydrogen protons within the magnetic field, whereupon some spins in the low-energy state absorb this energy and change to the high-energy state. The net effect of these excitation pulses is to tip the net magnetization into the transverse plane (Figure 4(a) and

Figure 3 Net magnetization. In the strong magnetic field of the MRI scanner, slightly more than half of the protons align their axis of precession parallel to the magnetic field, while slightly less than half are antiparallel. This difference results in a net magnetization, labeled **M**, along the direction of the magnetic field. Reproduced from Huettel SA, Song AW, and McCarthy G (2009) *Functional Magnetic Resonance Imaging*, 2nd edn. Sunderland, MA: Sinauer.

4(b)), where it oscillates at the resonant frequency of the precessing protons. In a process known as reception, the changing net magnetization induces corresponding oscillations in surrounding detector coils (**Figure 4(c)**); these oscillations are known as the MR signal.

Once the excitation pulse ceases, protons lose energy to their surrounding environment, leading to a recovery of the longitudinal component of the net magnetization. This occurs over several seconds, depending on a tissue- and field strength-specific time constant known as T_1 . Simultaneously, interactions between protons reduce the coherence in their precession, which in turn leads to a decay in the transverse component of the net magnetization (and thus a decay in the MR signal). This occurs within a few hundreds of milliseconds following the excitation pulse, as characterized by another time constant

known as T_2 . Finally, inhomogeneities in the magnetic field will cause protons to precess at different frequencies, which has an additive effect on top of T_2 spin interactions and is characterized by a third time constant T_2^* . This final time constant forms the basis of the BOLD contrast used in nearly all fMRI studies.

To create images, MRI scanners use a combination of radiofrequency excitation pulse(s) and patterned changes in magnetic gradients, collectively known as a pulse sequence. The elements incorporated into the pulse sequence depend upon the type of image to be collected. fMRI sessions typically collect two-dimensional images that comprise 64×64 volume elements (voxels), each a cube or rectangular prism a few millimeters on each side. An initial magnetic gradient causes systematic changes in precession frequency along one direction, and then an

Figure 4 A schematic representation of excitation and reception. (a) When protons are placed in an external magnetic field, usually labeled B_0 , more will be at the low-energy state (orange) than at the high-energy state (blue). (b) If an excitation pulse is applied at the resonant frequency of the protons, some will absorb that energy and jump to the high-energy state. (c) But, after the excitation pulse is turned off, some of the protons in the high-energy state will return to the low-energy state, releasing the energy they earlier absorbed. Reproduced from Huettel SA, Song AW, and McCarthy G (2009) *Functional Magnetic Resonance Imaging*, 2nd edn. Sunderland, MA: Sinauer.

excitation pulse excites protons selectively within a prescribed slice of tissue. To distinguish spatial information within that slice, magnetic gradients in the other two directions are rapidly cycled on and off in prescribed patterns while the MR signal is continually sampled. Each sample provides information about a different spatial frequency component of the image, and different pulse sequences use different patterns of gradients (e.g., echo-planar imaging: back and forth; spiral imaging: sinusoidal). Regardless of the pulse sequence, two parameters are important. The echo time (or TE) is the time between the excitation pulse and the recording of maximal MR signal; to give maximal T_2^* contrast for fMRI, TE values are typically a few tens of milliseconds. The time between successive excitations is known as the repetition time (TR); it depends upon how many slices are to be collected and the characteristics of the pulse sequence, including TE. Most fMRI studies sample the entire brain using 20 or more individual slices, with a TR between 1 and 3 s.

Blood Oxygenation Level-Dependent (BOLD) fMRI

fMRI does not measure neuronal activity directly. Instead, it measures metabolic changes associated with neuronal activity. Note that the brain represents only 2–3% of the body's mass but consumes about 20% of the body's energy, primarily in support of the integrative (dendritic) and signaling (axonal) activity of neurons. Neuronal activity involves rapid changes in the electrical potentials of cell membranes, primarily attributable to movements of ions through membrane channels, and restoring those membranes to their baseline potential requires considerable energy, perhaps 80% or more of all consumed by the brain. Metabolic sources of energy include glucose and oxygen, both supplied by the vascular system. However, the vascular supply of blood is imperfectly coupled to the increased metabolic demands of neurons, both in spatial specificity and in quantity. Following activity of even a spatially precise population

of neurons, there is increased blood flow throughout the surrounding brain, as much as several millimeters or more from the active neurons. Also, because the arterial system supplies more oxygen than can be extracted immediately by the capillaries, there is an increase in the amount of oxygenated hemoglobin and a decrease in the amount of deoxygenated hemoglobin in venous blood. These changes in blood flow and especially blood oxygenation suggest potential markers for brain function.

By the early 1980s, researchers had recognized that the relative oxygenation of blood (in vitro) influenced its

T_2^* decay constant. Later that decade, Ogawa and colleagues found that manipulating the proportion of blood oxygen indeed altered the visibility of neural blood vessels on T_2^* -weighted images. The effect discovered by Ogawa came to be labeled as blood oxygenation level-dependent contrast, or often simply BOLD contrast (**Figure 5**). Several groups began to explore whether this endogenous form of contrast could be used to create images of brain function. (Note that, at the same time, several fMRI studies used exogenous contrast agents, typically based on the injection of compounds containing

Figure 5 BOLD contrast. Under normal conditions, oxygenated hemoglobin is converted to deoxygenated hemoglobin within the capillary bed, resulting in a darkening of T_2^* images (a). But, when neurons become active, there is an increase in the supply of oxygenated hemoglobin. This causes a decrease in the amount of deoxygenated hemoglobin, which in turn results in brightening on T_2^* images (b). Reproduced from Huettel SA, Song AW, and McCarthy G (2009), 2nd edn. *Functional Magnetic Resonance Imaging*. Sunderland, MA: Sinauer.

the element gadolinium. The use of contrast agents remains important for many clinical uses of fMRI, but typically not for research studies because of the risks associated with injections and the toxicity of the agents.) The first BOLD fMRI studies, which were published in 1992, provided proof that this new technique could obtain images of activation in primary motor and visual cortices. Over the subsequent years, researchers extended the reach of BOLD fMRI to new domains, including attention, memory, decision-making, and other complex functions.

Only recently has there been significant progress toward understanding the neurobiological origins of the BOLD signal. Recall that the energy demands of the brain are primarily attributable to neuronal activity, specifically the restoration of membrane potentials. However, it was long unclear what aspect of neuronal activity was best correlated with BOLD signal: axonal action potentials, dendritic postsynaptic potentials, or both. Simultaneous measurements of fMRI BOLD signal and electrophysiological activity – originally in monkeys and more recently in humans – have indicated that BOLD signal contrast arises primarily from metabolic demands of postsynaptic potentials, with a lesser contribution following action potentials. In particular, synchronized dendritic activity (perhaps in particular frequency bands) across populations of neurons seems to be most closely associated with the BOLD signal.

Collecting, Processing, and Analyzing fMRI Data

Most fMRI experiments attempt to answer questions about brain function: for example, “What brain regions support a given cognitive process?” “How do two (or more) regions interact during performance of a particular task?” or “What differences in brain function predict whether individuals will have a specific trait?” The physical and physiological properties described in the previous sections establish important constraints upon the design and analysis of fMRI experiments. Fortunately, substantial experimental data indicate that the measured MR signal can be modeled as a linear convolution of neuronal activity (e.g., represented as impulses at the time of cognitive processing) with a standardized function of the BOLD hemodynamic response. Because of this linear-system framework, researchers can construct statistical tests that evaluate whether the activation from a brain region matched the neuronal activity predicted from their experimental design.

Most fMRI experiments adopt one of two sorts of experimental designs. (1) Blocked designs present stimuli or tasks for prolonged intervals, with the goal of evoking an extended period of steady-state neuronal activity. This

provides good power for detecting activated brain regions, but precludes inferences about the timing of activity. (2) Event-related designs present stimuli or tasks as a series of discrete, punctate events; these designs allow individuation of different effects embedded within complex experimental paradigms. Because they do not evoke the sustained activity of a blocked design, event-related designs have reduced detection power. However, recent work using genetic algorithms and numerical optimization has allowed creation of event-related designs that approach the detection power of blocked designs, while still allowing separation of responses to individual event types.

Once collected, fMRI data are usually subjected to a series of steps known as preprocessing to measure and remove unwanted variability. Initial temporal and spatial preprocessing steps correct for variability both in the timing of slice acquisition and in the spatial position of voxels. To minimize changes in head motion, researchers apply rigid-body transformations that attempt to minimize the error between each volume and a reference volume (e.g., the first in the data set). Comparisons across subjects are facilitated by normalizing the fMRI into a standard stereotaxic space, usually through a combination of linear and nonlinear transformations. Temporal filtering can minimize the contributions of several forms of noise, such as physiological variability (e.g., respiration) or slow, temperature-related changes in the strength of the magnetic field. Spatial filtering (i.e., smoothing) can reduce apparent noise and increase the validity of comparisons across subjects.

Data Analysis

Analyses in fMRI experiments can be either data-driven or hypothesis-driven. In data-driven analysis, which are only found in a minority of fMRI studies, the researcher identifies regularities present in the experimental data. Common approaches include independent components analysis, partial least squares, and intersubject correlations. Data-driven analyses are largely exploratory, in that they are intended to discover systematic but unexpected BOLD signal changes, which in turn suggest future topics for research. In contrast, hypothesis-driven analyses are intended to test specific predictions about the relations between an experimental task and an evoked BOLD activation. Most hypothesis-driven analyses use a variant of the general linear model to evaluate whether and how different cognitive processes contribute to the observed pattern of fMRI activation. The cognitive processes (or sets of processes) are modeled according to their hypothesized timing and duration of neuronal activity and then convolved with one or more basis functions that can approximate the fMRI hemodynamic response. The resulting model contains both experimental

regressors associated with cognitive processes of interest and nuisance regressors associated with task-irrelevant variation (e.g., head motion). A statistical program then calculates what combination of regression weights best predicts the experimental data. Data from different subjects is combined using fixed- or random-effects approaches; for most experiments, random-effects approaches are preferable because they allow extension of the results to the population from which the subject sample is drawn.

After statistical values are determined for each brain voxel, typically using the regression approaches described above, researchers must determine which of those voxels exhibit real experimental effects. Because a typical fMRI data set contains tens of thousands of voxels, conventional statistical testing (e.g., using a threshold probability of .05) will lead to an enormous number of Type I errors (false positives). Yet, using very strict correction factors (e.g., Bonferroni comparison) may cause the researcher to miss many regions with true activity (e.g., making Type II errors, or false negatives). A common compromise between these extremes is to adjust the correction factor based on the data's spatial autocorrelation, which can result from many sources: the spatial extent of activity, hemodynamic spread, smoothing during preprocessing, and variability across subjects. For fMRI data, the true number of independent comparisons can be orders of magnitude smaller than the number of voxels. Another, nonexclusive approach is to require clusters of activation to reach a particular size (e.g., 10 or more active voxels) to be counted as significant. The final outputs of fMRI analyses are maps indicating which brain voxels exhibited BOLD signal changes consistent with the cognitive processes manipulated in the experiment.

Displaying and Interpreting fMRI Data

A striking image of a high-resolution brain with colored patches (**Figure 6**) can suggest a photograph of the brain in action. The apparent detail of the background MRI images – or three-dimensional renderings – seemingly implies exquisite spatial resolution. And, a colored area of activation can be interpreted as the single module that supports some particular process, whether perceiving faces, making decisions, or evaluating numbers. All of these intuitions are false. The images arising from fMRI experiments are not photographs; they reflect the statistical confidence that a particular brain region expresses a particular function. Bright colors usually indicate regions where there is strong evidence that the experimental manipulation affected the BOLD signal, while uncolored regions lacked any significant statistical effect. The resolution of fMRI maps is relatively coarse, both because the images are usually acquired at 3–5 mm

Figure 6 fMRI data displayed on a high-resolution rendered brain. Shown are maps of fMRI activation derived from a visual perception task, here displayed on a high-resolution brain that has been rendered into a three-dimensional surface. Part of the parietal lobe has been cut away to show deeper brain structures. The colors represent areas of statistically significant activation, with the red to yellow colors indicating regions in the brain's fusiform gyrus associated with the perception of photographs of human faces, and the blue to white colors indicating regions in the brain's parahippocampal gyrus associated with the perception of photographs of outdoor scenes.

resolution and because preprocessing algorithms lead to substantial further smoothing, compared to the potentially sub-millimeter resolution of structural MRI. And, the identification of a single active region does not rule out the possibilities that many other regions may contribute – or that the experiment may not have sufficient power to identify other effects.

Future Directions

fMRI has become a dominant – and ubiquitous – research method in human cognitive neuroscience. The collection of fMRI data has become so pervasive that new MRI scanners, even those for clinical use, come equipped with hardware, pulse sequences, and online analysis programs for fMRI experiments. Given this maturity, from where will the next advances in fMRI arise? One possibility is increased field strength. In the early years of fMRI, there was a continual push toward high-field (i.e., >1.5 T) scanning. Now, 3 T and higher-field machines are common, both in research and clinical settings, and further improvements in field strength seem likely to be

incremental at best. Another possibility is improved spatial and temporal resolution. While some new techniques have arisen (e.g., the growth of spiral imaging), current fMRI data acquisition is – to a first approximation – largely similar to that of a decade ago. The stability of fMRI technology does not mean that no future advances are likely. In particular, simultaneous multiple-coil recording promises to allow researchers to reduce the time required to collect fMRI images and, more importantly, increase image quality. Yet, even this will not revolutionize BOLD fMRI experimentation. Instead, the main advances in fMRI will come from improved experimental designs, new forms of data analysis, and novel combinations with other techniques, from electrophysiology to spectroscopy. Regardless of whether some (or all) of these new developments take shape over the coming years, it seems clear that fMRI will continue to be a central technique in the study of the human brain.

Symbols

$B_0(s)$	magnetic field experienced by sample
$k_a, k_d, k(E)$	rate constants for activation, deactivation, reaction
k_{uni}	macroscopic pseudo-unimolecular rate constant
α	shape factor
κ_s	(sample) volume susceptibility
σ^{NMR}	rotationally inelastic cross section

NMR spectroscopy has been used to study many aspects of the physics and chemistry of molecules in the gas phase for more than 50 years. The third report of the observation of the magnetic resonance phenomenon, which was published in 1946, described a study of H_2 gas. The signal/noise ratio obtained from a 10 atm H_2 sample (line width 600 ppm at 0.68 T) was $\sim 15/1$ in that study. Nuclei in larger molecules have longer relaxation times and in many cases produce NMR spectra with natural line widths of less than 1 Hz. It is possible to obtain 1H and ^{19}F spectra with good signal/noise ratios from gases present at partial pressures of less than 1 torr. With this sensitivity, NMR spectroscopy can be used to address many questions about molecular interactions and dynamics in the gas phase. Experimentally measured chemical shifts and spin–spin coupling constants of gas-phase molecules are a benchmark for theoretical calculations of NMR parameters. Temperature- and pressure-dependent relaxation rate constants, T_1 , T_2 , and $T_{1\rho}$, have been measured for several different nuclei in diatomic and small polyatomic molecules in the gas phase. These data provide information about relaxation mechanisms, rotationally inelastic collision cross sections, coupling constants and intermolecular forces. NMR spectroscopy is an important tool for studying hydrogen

bonding in the gas phase. Thermodynamic parameters for keto–enol tautomeric equilibria and conformational equilibria of gases have been determined from measurements of temperature-dependent relative intensity ratios. Temperature- and pressure-dependent rate constants for low-energy intramolecular chemical exchange processes of gases including conformational interconversion, ring inversion and Berry pseudorotation have been measured using NMR spectroscopy. The motion of xenon atoms diffusing in zeolite matrices and the motion of gas-phase molecules in protein cavities can be studied using NMR spectroscopy. Gas-phase NMR spectroscopy can be used to study chemical reactions involving volatile species. Density-dependent chemical shielding, gas-phase relaxation and the applications of gas-phase NMR spectroscopy to chemical exchange processes have all been reviewed (see Further Reading).

Principles

Gas-Phase Chemical Shifts and Coupling Constants

The general features of high-resolution NMR spectra of gases resemble those of liquids, but the actual resonance frequencies in the gas phase and in solution are different owing to differences in the local environment. A gas sample has a smaller bulk magnetic susceptibility and weaker intermolecular interactions than a liquid. The bulk magnetic susceptibility difference causes the entire gas-phase NMR spectrum to be offset a few ppm from that of the corresponding liquid. The direction and magnitude of the offset depend on the magnetic field strength, the shape of the sample, its orientation in the magnetic field and its chemical composition. The magnetic field experienced by the sample, $B_0(s)$, is $B_0(s) = B_0[1 + (4\pi/3 - \alpha)\kappa_s]$, where B_0 is the applied magnetic field, κ_s is the volume susceptibility, a negative

quantity which is much smaller for a gas than for a liquid owing to density differences, and α is a shape factor that is zero for a cylinder aligned along the magnetic field axis and 2π for a cylinder aligned perpendicular to the field axis. For the parallel arrangement of a cylindrical sample in a 7.2 T superconducting magnet, the gas-phase spectrum is shifted a few ppm to higher frequency from the spectrum of the corresponding liquid.

In the gas phase, intramolecular factors primarily determine the relative resonance frequencies of the nuclei in a molecule. In a liquid, intermolecular interactions are also an important factor and the relative resonance frequencies of nuclei located at different sites within a molecule can be phase dependent. The largest phase-dependent shifts in relative resonance frequencies occur for nuclei in positions near the molecule's exterior and for nuclei capable of strong intermolecular interactions such as hydrogen bonding. **Figure 1** shows gas-phase ^1H NMR spectra of a series of alcohols obtained at 421 K. The major difference between these spectra and those of the corresponding liquid alcohols is the position of the hydroxyl proton resonance which, in each case, is near 0 ppm relative to gaseous TMS. The hydroxyl proton resonances of the corresponding alcohols in the liquid phase are several ppm lower than that of liquid TMS owing to participation in intermolecular hydrogen bonding. In contrast, the position of the resonances of the protons attached to the carbon atoms relative to TMS is similar for both gas-phase and liquid alcohols. For cases where intermolecular interactions are weaker, gas and solution spectra are more similar, but small relative changes are often observed. For example, the limiting ^1H methyl chemical shift differences for dimethylacetamide and dimethylformamide are slightly smaller in the gas phase than in solution.

The temperature and density dependences of the chemical shifts of nuclei of gas-phase molecules have received significant theoretical and experimental attention. The chemical shifts of most nuclei at a constant temperature exhibit a linear density dependence for moderate densities up to ~ 50 atm. Intermolecular effects are deshielding for almost all gas-phase molecules, except for molecules with π^* electronically excited states. The temperature dependence of the chemical shift of nuclei of gas-phase molecules at constant gas density can be used to probe the effects of rovibrational shielding. Deshielding occurs with increasing temperature as the population of rotationally and vibrationally excited states increases and the average internuclear distances in the molecule increase.

The phase dependence of spin-spin coupling constants is usually small since spin-spin coupling mechanisms are primarily intramolecular in nature. However, changes in conformational equilibria and molecular geometry can result from intermolecular interactions and can affect the magnitude of spin-spin coupling constants.

Figure 1 ^1H NMR spectra of gaseous *t*-butanol (a), isopropanol (b), ethanol (c), and methanol (d) at their respective vapour pressures at 421.8 K. Reprinted from Chauvel JP Jr and True NS (1985) Gas-phase NMR studies of alcohols. Intrinsic acidities. *Chemical Physics* 95: 435–441, © 1985, with permission from Elsevier Science.

For example, the magnitude of the spin-spin coupling between two nuclei separated by three bonds is dependent on the effective torsional angle and will be phase dependent if the conformational equilibrium established in the gas phase differs from that in solution. For substituted ethanes such as dimethoxyethane, the average $^3J_{\text{HH}}$ coupling constants in the gas phase have been measured as a function of temperature and used to determine conformational equilibria and barriers to internal rotation using models based on the Karplus equation. Solvent effects are determined by comparison with results of similar experiments performed on condensed-phase samples. Small phase-dependent differences in the $^1J_{\text{NH}}$ and $^2J_{\text{NH}}$ coupling constants of formamide have been observed and can be attributed to changes in bond lengths that occur upon solvation. For

molecules that do not exhibit conformational isomerism or form strong intermolecular interactions, gas-phase and solution-phase spin-spin coupling constants are very similar.

Relaxation

Nuclear spin-lattice relaxation of gas-phase molecules occurs primarily via the spin-rotation (SR) mechanism. The magnitude of the magnetic field generated by the rotational motion of the molecule changes at a rate that is dependent on the rotationally inelastic collision frequency. Scalar coupling of the nuclear spin angular momentum to this time-dependent field provides an efficient relaxation pathway that is generally not available in condensed phases where rotational motion is hindered. For medium-sized molecules, ^1H and ^{13}C T_1 values are typically on the order of a few hundred milliseconds and ^{19}F T_1 values are typically on the order of 10 to 100 ms at a gas pressure of 1 atm.

Figure 2 shows the characteristic nonlinear density dependence of T_1 in the gas phase. Most NMR

Figure 2 The density dependence of the proton T_1 of ammonia gas at 300 K. The density of an ideal gas at STP is defined as 1 amagat. The solid line is the best fit of a theoretical model that allowed for multiple relaxation times to the data. Reproduced with permission of the American Physical Society from Lemaire C and Armstrong RL (1984) Proton spin longitudinal relaxation time in gaseous ammonia and hydrogen chloride. *Journal of Chemical Physics* 81: 1626–1631.

relaxation studies of gases report gas densities in units of amagats where 1 amagat is the density of an ideal gas at 1 atm and 273 K, i.e. 2.687×10^{19} molecules cm^{-3} , or 44.612 moles m^{-3} . At the T_1 minimum, the collision frequency is approximately equal to the Larmor precession frequency of the nucleus. The T_1 minimum can be used to determine the rotationally inelastic cross section, σ^{NMR} , and the average spin-rotation (SR) coupling constant. The density-dependent T_1 data for the ^1H resonance of NH_3 , shown in Figure 2, is consistent with a σ^{NMR} of $105(8) \text{ \AA}^2$. This value is almost twice as large as the geometric cross section of the molecule, $60 \text{ \AA}^2$, indicating that long-range interactions are important in the relaxation process. The effective ^1H SR coupling constant of NH_3 is $20.3(0.1) \text{ kHz}$, considerably larger than the ^1H – ^1H dipole-dipole coupling constant in this molecule.

Relaxation via dipole-dipole interactions and quadrupolar interactions has also been observed for nuclear spins of molecular gases. Dipole-dipole relaxation is competitive with spin-rotation relaxation of H_2 in the gas phase. For H_2 , the SR coupling constant is $\sim 110 \text{ kHz}$ and the dipole-dipole coupling constant is 143 kHz . This mechanism has not been found to contribute significantly to spin-lattice relaxation of larger molecules, where dipole-dipole distances are greater. The lack of observable nuclear Overhauser enhancement (NOE) in gaseous benzene indicated that relaxation via dipole-dipole interactions is not significant at densities between 7 and 81 mol m^{-3} at 381 K. For ^{14}N in nitrogen gas, the dominant relaxation mechanism is through intramolecular quadrupolar interactions. Experiments on ClF established that there is a significant contribution to $T_{1\rho}^{\text{F}}$ from modulation through quadrupolar relaxation of ^{35}Cl and ^{37}Cl of $J(^{35}\text{Cl}\text{--F})$ and $J(^{37}\text{Cl}\text{--F})$. The dependence of $T_{1\rho}^{\text{F}}$ on the spin-lock field strength allowed values of these two spin-spin couplings to be obtained.

Dipole-dipole interactions occurring during collisions provide a relaxation mechanism for atoms in the gas phase. Xenon-129 atoms in the gas phase have spin-lattice relaxation times on the order of minutes which are dependent on gas density, temperature and the amount of other gases in the sample. For xenon-129 adsorbed in cavities inside zeolite matrices relaxation occurs via dipole-dipole interactions with hydrogen atoms that are bound to the sides of the cavities.

Methods

Sample Preparation

For many applications, gas-phase samples can be prepared using a routine vacuum line consisting of mechanical and diffusion pumps, a cold trap, thermocouple and capacitance manometer gauges and a manifold with

attachments for sample tubes and gas inlets. NMR sample tubes are either sealed with a glass torch or constructed with self-sealing top assemblies. Preparation of samples at elevated pressures requires quantitative transfer operations. With few exceptions, gas-phase NMR samples used to study conformational processes contained a volatile bath gas in addition to the sample molecule, which usually has a low vapour pressure. Molecules with low vapour pressures tend to behave nonideally even at very low pressures and this factor must be taken into consideration when converting measured gas pressures into densities.

Sample diffusion and convection are significant problems in temperature-dependent studies and in relaxation experiments using gases. In most NMR probes the heater is positioned below the bottom of the sample and the top of the sample protrudes above the spinner. With this arrangement a significant temperature gradient occurs along the length of a standard NMR tube when working at elevated temperatures. This causes convection in the sample and makes it impossible to establish, maintain and measure the temperature. Diffusion can cause significant line broadening at low pressures and can result in large systematic errors in relaxation measurements. To minimize these problems, short NMR tubes are frequently used for gas-phase studies. They provide better temperature control and minimize diffusion of magnetized molecules from the active volume region of the receiver during monitoring of the free induction decay. For relaxation studies of gases, the sample must be confined to the active volume of the receiver for accurate measurements of relaxation times and the tube length cannot exceed the receiver coil dimensions. Short tubes can be placed directly inside a standard size coaxial outer tubing to facilitate sample spinning (if required) or they can be attached to a spinner via a stem.

For samples containing total gas pressures of 3 atm and below, sample cells constructed from standard thickness 12, 10, or 5 mm o.d. NMR-quality glass tubing have been employed. Sample cells constructed from heavy-wall NMR-quality glass tubing, single-crystal sapphire and vespel can be used for studies of gases at pressures above 1 atm. Special precautions are necessary at all stages of assembling, testing and using any kind of high-pressure NMR apparatus because of the hazards involved. Samples in the 5–50 atm range can be prepared in small-diameter tubes with 2 mm thick walls that can withstand pressures of 50 atm. The maximum pressure is limited by the ratio of the outer diameter to the inner diameter of the tube. Pyrex and borosilicate glasses have been used. Xenon gas has been studied at pressures up to 200 atm in borosilicate glass (3.9 mm o.d./1.2 mm i.d.). Methane and ethane have been studied at pressures up to 300 atm in Pyrex tubes (5 mm o.d./0.5 mm i.d.). Sample cells constructed from single-crystal sapphire epoxied to

titanium flanges that attach to vacuum lines have been used to prepare samples containing gases at pressures up to about 130 atm. A newer design allows use with 5 or 10 mm tubes, is light enough to allow spinning in most spectrometers and allows attainment of proton line widths of 0.5 Hz in 300 MHz spectrometers. Heavy-walled Vespel tubes have been used to study reactive systems at elevated pressures. This polyimide material is resistant to chemical attack but heavy walls are required and after several pressurizations the tubes tend to deform.

Specially designed NMR probes capable of withstanding high internal pressures have been described. Improved sensitivity and resolution have been obtained with toroidal probes. They consist of a toroidal-shaped RF detector inside a pressure vessel with RF and gas connectors mounted on the top and bottom, respectively, and are useful for studying pressurized reactor effluent.

Spectral Acquisition

Gas-phase NMR spectra can be acquired using procedures similar to those employed for liquid samples. Most gas-phase NMR spectra are obtained without use of a frequency lock. The field drift of most superconducting magnets is only a few hertz per day and does not contribute significantly to observed line widths of spectra acquired in a few hours or less. The absence of a lock necessitates that shimming must be done by observing the magnitude and shape of the free induction decay. Inclusion of several torr of TMS gas ensures a free induction decay of adequate magnitude for shimming. For very high-resolution work or long runs, a deuterated bath gas such as neopentane- d_{12} or isobutane- d_{10} can be used, but the low sensitivity in the lock channel on most spectrometers requires the presence of a partial pressure of at least 0.5 atm of these molecules to achieve a stable lock.

Acquisition of gas-phase NMR spectra is facilitated by rapid spin-lattice relaxation. This is especially true for ^{13}C studies of gases where T_1 values can be hundreds of times shorter than in condensed phases and transients can be acquired much faster. However, relaxation times and mechanisms in the gas phase preclude many experiments involving intermolecular and intramolecular polarization transfer that are routinely performed on solution samples.

Applications

Specific applications of gas-phase NMR spectroscopy to research in heterogeneous catalysis, conformational dynamics and absorption processes in zeolites are described below. The application of gas-phase NMR spectroscopy

to many other research areas is described in the Further Reading section at the end of this article.

Heterogeneous Catalysis

Gas-phase NMR can be used to study the kinetics of reactions that consume or generate volatile species. For example, gas-phase NMR spectroscopy was used to follow the kinetics of the hydrogenation of *cis/trans* mixtures of perfluoro-2-butenes ($R=CF_3$) and perfluoro-2-pentenes ($R=C_2F_5$) over palladium supported on alumina (eqns [1] and [2]).

Samples were prepared in 12 mm NMR tubes and contained a total gas pressure of ~ 3.1 atm at 333 or 338 K. The time dependence of the composition of the sample was determined from ^{19}F NMR spectra. Since the T_1 values of all the ^{19}F nuclei present are short, it was possible to obtain spectra, the result of 16 transients, with a signal/noise ratio of 1000 in 2.9 s. The data obtained in these experiments would be very labour intensive to obtain by conventional chemical techniques. **Figure 3** shows typical data obtained in this experiment. The *erythro/threo* product ratio was the same as the starting *cis/trans* reactant ratio, indicating that the olefins did not isomerize during the reaction and hydrogenation of the *cis* olefins produces the corresponding *erythro* hydrofluorocarbons while hydrogenation of the *trans* olefins produces the corresponding *threo* hydrofluorocarbons. The rate of hydrogenation was faster for the *trans* isomer of both perfluoro-2-butene and perfluoro-2-pentene, with the rate constant ratio, $k_{\text{trans}}/k_{\text{cis}}$, ranging from 2 to 3.4. It was also found that the *cis* isomers are preferentially absorbed on the catalyst, a fact that may account for their lower relative reactivity.

Conformational Kinetics

For many gas-phase molecular processes with activation energies in the $5\text{--}20\text{ kcal mol}^{-1}$ range, temperature- and pressure-dependent rate constants can be obtained from

Figure 3 Time dependence of the concentrations of reactants and products of the Pd/Al₂O₃-catalysed hydrogenation of a 24.8/75.2% *cis/trans* mixture of perfluoro-2-pentene at 65 °C obtained by ^{19}F gas-phase NMR. Reprinted with permission from Kating PM, Krusic PJ, Roe DC, and Smart BE (1996) Hydrogenation of fluoroolefins studied by gas phase NMR: A new technique for heterogeneous catalysis. *Journal of the American Chemical Society* 118: 10 000–10 001. © 1996 American Chemical Society.

analysis of exchange-broadened NMR line shapes. Frequently, rate constants can be obtained with accuracy comparable to that obtained in the best liquid-phase studies. This technique can be applied successfully to gases that have at least 1 torr of vapour pressure at temperatures at which slow or intermediate exchange can be observed. Temperature-dependent gas-phase rate constants and kinetic parameters can be compared with similarly obtained parameters in condensed phases to determine the direction and magnitude of solvent effects on these processes. Gas-phase results also provide a critical test for theoretical calculations. The pressure dependence of rate constants for chemical exchange processes in the gas phase provides information on the microscopic dynamics of these processes in isolated systems.

Rate constants for the chemical exchange processes that occur in alkyl nitrites, cyclohexane, substituted cyclohexanes, sulfur tetrafluoride and formamide are pressure dependent. The mechanism for these thermally initiated, unimolecular gas-phase processes, reported by Lindemann in 1922, involves competition between the reaction and collisional deactivation of the critically energized molecule, A^* (eqn [3]).

where k_a , k_d and $k(E)$ are the rate constants for activation, deactivation and reaction. The rate constant for reaction, $k(E)$, is energy dependent. The solution of this mechanism yields the macroscopic pseudounimolecular rate constant, k_{uni} (eqn [4]).

$$k_{\text{uni}} = \frac{1}{[A]} \frac{d[A]}{dt} = \int_{E=0}^E \frac{k(E) \cdot k_a/k_d}{1 + k(E)/k_d[M]} dE \quad [4]$$

At large $[M]$ the integrand reduces to $k(E)k_a/k_d$ and k_{uni} is a constant. At small $[M]$ the integrand reduces to $k_a[M]$ and k_{uni} is a linear function of the gas density. The zero of energy is taken at the energy at threshold. The details of the fall-off curve, i.e. the rate constant k_{uni} as a function of gas density, provide information about intramolecular energy transfer in the critically energized molecule. If this is ergodic and rapid on a timescale that is short compared to the reaction rate constant, statistical theories such as RRKM theory can be used to calculate $k(E)$. The molecular conditions that favour statistical behaviour are high densities of states in the reactant and efficient coupling mechanisms. Reactions of large molecules at high internal energies can generally be modelled adequately with statistical theories. The processes that can be studied by gas-phase NMR spectroscopy occur at much lower energies where state densities are sparse and coupling mechanisms are inefficient. The shape and location of the experimental fall-off curves of chemical exchange processes provide a test of the applicability of statistical kinetic theories to these low-energy processes.

Figure 4 shows exchange-broadened gas-phase ^1H NMR spectra of *n*-propyl nitrite obtained at 240.6 K as a function of CO_2 bath gas pressures. Each sample contained 2 torr of *n*-propyl nitrite. Rate constants for the *syn-anti* conformational exchange process, obtained from the spectral simulations, range from 315 s^{-1} at 720 torr to 112 s^{-1} at 11.8 torr. The pressure dependence of these rate constants was compared with predictions using RRKM theory. The agreement obtained indicated that vibrational redistribution in *n*-propyl nitrite is statistical or nearly so at the average internal energy required for the *syn-anti* conformational interconversion process, which is $\sim 12 \text{ kcal mol}^{-1}$. The observed fall-off curve is dependent on the bath gas used in the study and relative collision efficiencies for activation of the conformational process can be obtained from studies that vary the bath gas. Smaller nitrites, SF_4 and formamide have lower state densities and have been the subjects of detailed analysis.

Absorption Processes in Zeolites

Several factors make xenon a very useful probe nucleus for studying absorption processes in microporous

Figure 4 Gas-phase ^1H NMR spectra of *n*-propyl nitrite at 240.6 K. The spectral region shown corresponds to the methylene protons attached to the carbon bonded to the oxygen. Samples contained 2 torr of *n*-propyl nitrite and various pressures of CO_2 . Spectral labels refer to the total sample pressure in torr. In each plot the top trace is the simulated spectrum, the middle trace is the experimental spectrum and the lower trace is the difference between the two. Reprinted with permission from Moreno PO, True NS, and LeMaster CB (1990) Pressure-dependent gas-phase ^1H NMR studies of conformational kinetics in a homologous series of alkyl nitrites. *Journal of Physical Chemistry* 94: 8780–8787. © 1990 American Chemical Society.

materials such as zeolites. It is chemically inert, monatomic and of a convenient size, and its chemical shift is very sensitive to environmental factors and is amenable to theoretical modelling. Two of the stable isotopic species of xenon, ^{131}Xe and ^{129}Xe , have magnetic moments. ^{129}Xe , which has a spin of $\frac{1}{2}$, a natural abundance of 26.44%, a receptivity 31.8 times greater than ^{13}C and T_1 values on the order of seconds, is the most extensively used. The effects of environmental interactions on the chemical shift of xenon have been modelled using grand canonical Monte Carlo simulations, allowing the determination of the cluster size of xenon in cavities in a zeolite from chemical shift measurements. A study of xenon adsorbed in AgA zeolite, which is a system of silicoaluminate cages containing charged Ag clusters separated by 8-membered Si–O–Si rings, demonstrated that up to 10 different cluster sizes could be

distinguished by their differences in chemical shifts. **Figure 5** shows static NMR spectra of ^{129}Xe in AgA zeolite. Spectral labels refer to the zeolite composition, dehydration temperature, and average number of xenon atoms per cage. Chemical shifts are referenced to xenon gas present in spaces between the crystallites. Exchange between cages is slow and the ^{129}Xe NMR spectrum consists of a series of lines corresponding to cages with different numbers of xenon atoms. The ^{129}Xe resonances from high field to low field have chemical shifts that range over 200 ppm and are assigned to cages containing from 2 to 8 xenon atoms. Xenon intercage exchange dynamics can be studied using 2D-EXSY experiments. If chemical exchange occurs on the order of the mixing time, off-diagonal cross peaks appear in the 2D spectrum between the sites involved in the exchange. The cross peaks provide information about the exchange pathways and

Figure 5 NMR spectra of xenon in AgA zeolite. The axis in each spectrum is labelled in ppm with 0.00 ppm corresponding to the chemical shift of xenon gas in the space between the crystallites in the sample. Spectral labels refer to the zeolite composition, sample preparation temperature, and the average number of xenon atoms per α cage. The progression of lines to lower field corresponds to resonances from 1 xenon atom per α cage to 8 xenon atoms per α cage, respectively. Reprinted with permission from Moudrakovski IL, Ratcliffe CI, and Ripmeester JA (1998) ^{129}Xe NMR study of adsorption and dynamics of xenon in AgA zeolite. *Journal of the American Chemical Society* 120: 3123–3132. © 1998 American Chemical Society.

their intensities are a function of the exchange rate constant. Rate constants for exchange between cages indicate that sorption energies decrease at higher loading.

One major new area of application of gas-phase NMR is the use of hyperpolarized inert gases such as helium or xenon as contrast agents in MRI studies, particularly of the lung. Hyperpolarized inert gases have also been used to probe gas storage in organosilica nanochannels. In addition, the use of ^{19}F NMR T_1 variation of SF_6 has been explored for lung studies and that of CF_4 has been used in investigations of nanopore size.

Objectives of Geological and Mineralogical Analysis

The earth sciences are rapidly and strongly evolving toward interpreting most geological questions using the tools of geochemistry and mineralogy. The foremost problem of geochemistry is to study the distributions, concentrations, and behavior of the naturally occurring elements in the earth as a complete system. The majority of geochemical questions center on the upper continental crust (UCC); studies commonly address interactions between phases (hydrosphere, lithosphere, atmosphere, biosphere). Geochemical studies often pursue pragmatic questions, such as locating and understanding the origins of economically important ore deposits (geochemical exploration) or measuring the disturbances associated with recent anthropogenic impacts (environmental geochemistry). Geochemical studies generally entail sample collection followed by analytical work; typical tasks are the determinations of major, minor, and trace elements, and the isotope compositions of selected elements. Major elements (> 1% by mass) in the UCC consist of O, Si, Al, Fe, Mg, Ca, K, and Na. Minor elements (100 ppm – 1%) in the UCC are Ti, H, P, F, Ba, S, Cl, and Sr. The remaining trace elements are present at < 100 ppm; several elements of significant economic importance (e.g., Ag, Au, Pt, Pd, and Rh) are present at average UCC concentrations well below 1 ppm.

The field of mineralogy pursues identification of individual minerals, and understanding their age/origin,

distribution, thermodynamic stability, and physical/chemical transformations. Minerals occur both as pure deposits and incorporated into solid-state mixtures of individual phases (rocks). Mineralogical studies typically entail field specimen collection or examination of archived collections, and analytical efforts consist of determining empirical formulas through elemental analysis, and identification of specific crystalline forms through physical properties (density, hardness, refractive index, luminescence, and diffraction of X-rays). Major mineral groups in the UCC consist of silicates, oxides, carbonates, sulfides, sulfates, phosphates, halides, and native elements. Many products of economic importance are derived from minerals in the UCC; examples include bauxite (Al_2O_3), gypsum (CaSO_4), and rutile (TiO_2).

The analytical tasks associated with geochemistry and mineralogy rely heavily on modern atomic spectroscopic techniques. These tasks can be broadly categorized as follows: (1) determination of elemental constituents; (2) isotopic analysis of selected elements; and (3) identification of specific mineral phases.

Techniques for Determination of Elemental Constituents

Major, minor, and trace elements can be determined in geological samples using a variety of techniques that compete with and complement each other. The four techniques that are used most widely are inductively coupled plasma mass spectrometry (ICPMS), inductively coupled plasma atomic emission spectroscopy (ICPAES), flame and furnace atomic absorption spectroscopy (AAS), and X-ray fluorescence spectroscopy (XRF). Although many other techniques have been used, historically or in a specialized research mode, these four techniques probably account for the vast majority (> 90%) of all elemental constituent measurements in geochemistry/mineralogy applications. Each is described briefly, and then comments about the strengths and weaknesses of each are presented.

ICPMS

Arguably, ICPMS is now the single most important technique for elemental analysis, and this is even more evident in geochemical analysis than in other applications. ICPMS uses an Ar gas plasma to generate gas-phase elemental ions; the ions are sampled from the atmospheric pressure plasma into a high-vacuum

Figure 1 Schematic representation of a quadrupole ICPMS system; the small dots represent sample aerosol and the resulting atoms and ions. Only a small fraction (0.01–0.1%) of the atoms introduced to the plasma are ultimately counted as signal events; the remaining atoms are lost during the analytical process.

environment using a differentially pumped interface with two sequential ~ 1 mm apertures. The ions extracted are analyzed by mass spectrometry; quadrupole, magnetic sector, and time-of-flight mass analyzer-based instruments are available commercially. The quadrupole system is the simplest, most widely used, and least expensive option and has good performance for general elemental analysis (**Figure 1**). Magnetic sector ICPMS is preferred in applications demanding highest sensitivity, freedom from interfering (polyatomic) ions, or high-precision isotopic measurements. The time-of-flight ICPMS, which is not widely used, is ideally suited for transient multielement signal measurements. Liquid samples are introduced as aerosols from nebulizer-spray chamber systems; gases can be introduced directly to the plasma, and solids can be introduced without dissolution via slurry nebulization or laser ablation. ICPMS is well suited for qualitative/semiquantitative screening work, quantitative analysis, and isotopic analysis. Qualitative identification of the elements present is performed by comparison of the mass spectra to individual elements' natural isotopic compositions. Quantitative analysis is possible by calibrating ion intensities versus concentration, with the caveat that internal standardization or isotope dilution is generally required. Isotopic analysis is possible using signal ratios of interference-free isotopes, after blank subtraction and corrections for mass discrimination (i.e., unequal extraction or transmission efficiency for different masses). Detection limits are much less than microgram-per-liter values in most cases and are often blank limited. ICPMS offers very broad elemental coverage, with only a few inaccessible elements (e.g., F); performance is generally superior for higher-mass elements having lower first ionization energies. The two main limitations of ICPMS are matrix effects ('space charge' effects originating from matrix dependency of the ion extraction/transmission efficiency) and the frequent presence of polyatomic ions of the same nominal mass as

the analyte ion. Both limitations are reasonably well understood and overcome by a range of strategies. Matrix effects are minimized by working at relatively low total dissolved solids in liquid samples ($<0.2\%$), and through internal standardization or isotope dilution. Interfering ions of the same nominal mass (e.g., $^{40}\text{Ar}^{35}\text{Cl}^+$ on $^{75}\text{As}^+$) can be dealt with by chemical separations before sample introduction, the use of post-plasma collision/reaction cells for selective attenuation of undesired ions, or by exploiting high resolving powers possible with magnetic sector ICPMS devices. An overview of the range of applications of magnetic sector ICPMS is given in the study by Gäbler. ICPMS is well suited for the routine analysis of the minor and trace analytes and is capable of generating isotope ratio data. Several monographs give overviews of ICPMS; a good introduction is given in the study by Thomas, with a more comprehensive treatment in the book *Inductively Coupled Plasma Mass Spectrometry* by Montaser.

ICPAES

ICPAES uses the same Ar plasma and sample introduction methods as ICPMS, and actually predates ICPMS as an established technique in geological analysis. Commercial ICPAES instruments have been available since the early 1970s. In ICPAES, the photons generated by electronically excited atoms or ionized atoms are viewed through an optical spectrometer; 'atom' and 'ion' lines, respectively, are used for qualitative and quantitative measurements. The spectral lines are observed on top of relatively high continuum emission generated by $\text{Ar}^+ - \text{e}^-$ recombination processes. Spectral overlaps within the resolution possible (0.005–0.03 nm) are commonplace, and several elements such as Ni, Fe, and W generate complex line-rich spectra. Three types of optical spectrometers have been widely used in commercial instruments: Rowland Circle 'simultaneous'

polychromators with fixed wavelength detector channels; versatile but slow 'sequential' Czerny–Turner monochromator-based instruments that measure one line at a time; and two-dimensional imaging spectrometers that simultaneously measure entire spectra or selected spectral windows using a planar charge-coupled device detector. The latter type of spectrometer now dominates the modern ICPAES instrumentation market. The main limitation of ICPAES is the high continuum emission background; this constrains detection limits to low microgram-per-liter values for most elements, although a few elements produce submicrogram-per-liter detection limits. The high continuum background in ICPAES requires the use of background correction measurements in the immediate vicinity of each spectral line, and the background level is susceptible to matrix elevation or suppression. However, in the absence of interfering spectral lines, ICPAES can be considered to be a much more 'robust' technique than ICPMS, since matrix effects are much less severe, and simple external calibration (without internal standards) is generally acceptable. ICPAES has relatively broad elemental coverage, including nonmetals, although detection limits are poor for important specific elements such as Th or U. ICPAES systems are generally easier to maintain and operate than ICPMS. It is also pointed out that, in ICPAES, the spectrometer is indirectly observing photons emitted by the sample, rather than physically extracting and counting ions from the plasma as is done in ICPMS. An older review that critically compares ICPAES with ICPMS for applications in the earth sciences is given in the study by Jarvis and Jarvis.

AAS

Atomic absorption techniques are based on the absorption of atomic spectral lines by gas-phase atoms in their ground electronic states. The atomic vapor, $M(g)$, is usually generated thermally in a flame (flame AAS) or graphite furnace tube (furnace AAS), although in a few cases (most notably Hg), the atomic vapor is generated by chemical reduction to $M(g)$. The instrument consists of an 'atom cell' arrangement for generating $M(g)$, an atomic emission light source specific for each individual element to be determined, and an optical spectrometer for selecting an appropriate spectral line. AAS is, in most implementations, constrained to one-element-at-a-time determinations. The flame AAS technique dates to the early 1950s, and became well established in the 1960s as a routine method with commercial instrumentation. Flame AAS is usually performed on dissolved samples, and is a simple, very rapid, and generally robust interference-free technique for analysis of selected elements with simple external standardization with matrix-matched solutions. However, flame AAS has high detection limits in most

cases (several micrograms per liter to milligrams per liter) and consumes copious volumes of sample solution (typically several milliliters per element determined). Throughput may be as high as two to three single-element determinations per minute. Furnace AAS is better suited for achieving lower detection limits and for analysis of smaller samples (5–100 μ l); the ground-state vapor is formed in graphite or metal tubes by resistive heating with appropriate controlled temperature programming. Furnace AAS generally requires 2–3 min per determination, and moreover, the large matrix effects usually necessitate calibration by the method of standard additions (MSA). Hence, furnace AAS is cumbersome and only capable of generating five to six single-element determinations per hour with MSA. Both flame and furnace AAS have poor elemental coverage; many elements of importance in geochemistry and mineralogy cannot realistically be determined, as it is difficult or impossible to generate $M(g)$ at the modest 2000–3000 °C temperatures in the atom cell. These 'refractory' elements include many of the transition metals (e.g., Zr, Nb, Ta, Hf, and W), the lanthanides (La–Lu), and actinides (Th, U). Owing to their broader elemental coverage and rapid multielement capabilities of ICPAES and especially ICPMS, these plasma-based techniques have largely displaced most uses of AAS in geological analysis. Nevertheless, AAS maintains a place where it can meet the analytical performance needed with a simpler lower-cost system. For geological samples, AAS is best suited to the analysis of major and minor elements (Na, K, Mg, Fe, Mn); in only a few situations (e.g., Cu), flame AAS provides enough sensitivity for determining trace elements without preconcentration at levels typical of the UCC. Flame AAS, however, is applicable to situations where elevated concentrations are present, such as geochemical exploration studies, and the characterization of anthropogenic contamination from selected elements (e.g., Cu, Cd, Pb, and Zn). An excellent compendium of AAS applications and techniques is given in the AAS 'cookbook' from Perkin-Elmer.

XRF

X-ray absorption and emission spectra originate from electronic transitions of inner-shell electrons; these transition energies are only slightly affected by the physical or chemical form of the element of interest. The transition energies of K ($n=1$) and L ($n=2$) inner-shell electrons are closely related to the atomic number, as was discovered in the early twentieth century by Moseley. XRF spectra can be generated by bombarding a sample with a focused monochromatic X-ray beam; monochromatic X-rays are produced by ~ 10 –100 keV electron bombardment of a metal target in an X-ray tube. The incident X-rays interact with the sample atoms, exciting

inner-shell electrons into higher energy states. Subsequently, X-rays of other energies, characteristic of the elements present in the sample, are emitted. Similar spectra can be generated using *in vacuo* electron bombardment of solid samples, as is done in electron microscopy. X-ray spectra generated by either method afford both qualitative and quantitative information; qualitative indication of the presence of an element stems from the appearance of expected X-ray lines of specific energies. Quantitative analysis is possible because the emission intensity is proportional to atomic concentration, although matrix effects exist due to differences in sample transparency to the incident electrons/photons or emitted X-rays. The matrix effects are strongly associated with the sample's bulk density, geometry, and average atomic number; several successful computational methods such as 'fundamental parameters' allow for routine, robust quantitative analysis. Two types of spectrometers are in common use: 'dispersive' spectrometers based on diffracting crystals, that is, an X-ray monochromator, and 'nondispersive' spectrometers based on semiconductor detectors with energy-discrimination capabilities. The latter are more common and less expensive; these are usually referred to as 'energy-dispersive' spectrometers. Both XRF and its closely related technique, scanning electron microscopy with energy-dispersive X-ray analysis (SEM-EDX), are well suited for analysis of major and minor elements, with some capabilities for trace (<100 ppm) measurements. XRF and SEM-EDX have two strong points: first, SEM-EDX has excellent capabilities for microanalysis with spatial resolution <1 μm limited by the focusing of the electron beam and the sample interaction volume. Second, XRF and, for conducting samples such as metals, SEM-EDX are non-destructive. These techniques can be used as an initial screening analysis without preparation, or when non-destructive analysis is strictly necessary (i.e., in archaeometry). Both XRF and SEM-EDX have broad elemental coverage (elements with $Z = 11$ and higher are routinely analyzed), although some spectral overlaps exist between the K lines of light elements and the L lines of heavier elements. An overview of the applications of XRF to the analysis of environmental samples (soils, water, sediments) is given in the study by Melquades and Appoloni.

Isotopic Analysis of Selected Elements

Many elements exhibit variance in isotopic compositions from several natural effects (fractionation, radiogenic parent-daughter pairs, and decay-series disequilibria). The traditional 'stable isotope ratio mass spectrometry' approach for light element fractionation studies (H, C, N, O, S) uses gas-phase sample introduction, electron

impact ionization, and analysis with specialized magnetic sector instruments. Elements with one or more radiogenic isotopes (Sr, Nd, Hf, Pb) have been analyzed by thermal ionization mass spectrometry (TIMS) for several decades. TIMS is still commonplace and an excellent referee technique, although magnetic sector ICPMS with a multiple collector array (MC-ICPMS) has emerged as an excellent complement for precise isotopic analysis of the traditional TIMS elements and many others. In MC-ICPMS, the simultaneous counting of multiple ion beams at the flat-top peak summits obviates most of the short-term signal fluctuations associated with the relatively noisy ICP ion source. When sufficiently large samples, on the order of >100 ng of the element in question, are analyzed, high ion currents are measured on Faraday cup detectors and data are limited by counting statistics; MC-ICPMS ratio data of better than 0.01% relative accuracy are routine. MC-ICPMS is superior to TIMS in terms of sample throughput, although the former is extraordinarily sensitive to polyatomic ion interferences; chemical separations of the target element are usually required before analysis. In the past decade, MC-ICPMS has spawned the intense investigation of many 'nontraditional' elements such as Fe, Cu, Zn, Mo, Cd, and Hg. The resultant isotopic data are proving invaluable in revealing new insights into global element cycles, biogeochemistry, chronology, and environmental geochemistry.

Mineral Phase Identification

Atomic spectroscopy has much to contribute in mineralogy and identification of individual mineral phases. Techniques such as X-ray diffraction (XRD) identify macro amounts of pure crystalline solids; however, in microanalysis, SEM-EDX or 'microprobe' (SEM coupled with a wavelength-dispersive X-ray spectrometer) has been traditionally used. In the past two decades, however, these approaches have been complemented by the emergence of laser ablation ICPMS (LA-ICPMS) for direct microanalysis of solid samples. LA-ICPMS employs a focused UV laser (266, 213, or 193 nm) in pulsed mode to generate an aerosol of sufficiently small size (<2–3 μm) to be transported and processed in the ICP. Although useful for bulk analysis, the forte of LA-ICPMS is in semiquantitative microanalysis, with elemental and isotopic analysis of specific mineral grains being possible.

Dissolution Methods

Although several of the above-mentioned techniques are suitable for direct analysis of solids, dissolution of solid samples is necessitated in many circumstances and is common practice in ICPMS, ICPAES, and AAS.

Dissolution offers the advantage that the solution is representative of a large sample mass; it allows for effective sample-spike equilibration in isotope dilution ICPMS and generates a homogeneous solution for chemical separations. Dissolution of solid samples produces aqueous solutions conveniently handled in these techniques and greatly simplifies calibration. An important consideration is to determine whether a 'total dissolution' approach or a 'leach' treatment is more appropriate for the task at hand. Total dissolution (using HF-containing mineral acid mixtures, or molten salt fusion) is preferred for determining the complete elemental composition irrespective of phases and mineralogy; however, leach procedures are often preferable for detecting secondary mineralization in exploration. Leaching with dilute mineral acids is often better at detecting the anthropogenic component of pollutants such as Pb. Selective and sequential extractions are often used to operationally define the physicochemical speciation of target elements, compartmentalizing the target's inventory into associations such as 'exchangeable,' 'carbonate,' 'Fe-Mn oxide,' 'organic matter,' and 'residual.' Either total dissolution or leaching approaches generate aqueous solutions conveniently suited for AAS and ICP sample introduction hardware.

Example of an Application in Geochemistry

An example of a geochemical study integrating several types of atomic spectroscopy techniques is the investigation of atmospheric Pb deposition from anthropogenic versus natural sources in a peat bog. This study by Le Roux et al. sampled and dated a ~4000 year peat record from an ombrotrophic bog near Manchester, UK. All nutrients in ombrotrophic bogs are derived entirely from atmospheric deposition; hence these bogs serve as excellent records of baseline versus anthropogenic deposition of pollutants. After sectioning and grinding, XRF was used for nondestructive determination of Sr, Ti, and Pb; peat samples were completely digested with HNO₃-HBF₄, and Pb concentrations were determined by furnace AAS. Pb ratio data were measured by TIMS and ICPMS; for the latter, an MC-ICPMS and a single-collector magnetic sector ICPMS were used. The Pb ratio data indicated the dominance of English ore sources during pre-Roman, Roman, and Medieval time frames, along with sharp increases in Pb concentrations and isotopic shifts stemming from the Industrial Revolution. Pb deposited during the modern post-Industrial Revolution era exhibited a ²⁰⁶Pb/²⁰⁷Pb of 1.14–1.16 versus pre-Industrial Revolution ratios of ~1.18; in coincidence, Pb concentrations in the peat also rose from <10ppm to as high as ~500 ppm.

Example of an Application in Mineralogy

Ramos et al. studied Sr isotopic compositions in individual mineral phases in basalts using LA-ICPMS. With laser ablation, no opportunity exists for conducting chemical separations of interfering elements, unlike solution ICPMS. Accordingly, a wide variety of potential interfering ions were carefully evaluated and appropriate corrections established where needed. The resulting method demonstrated equivalency with dissolved/separated phases. Individual phases studied included carbonates, plagioclases, and pyroxenes.

Introduction

Glow discharge (GD) plasmas have been applied as ionization sources for mass spectrometry (MS) analysis for over 80 years. In fact, during the first two decades of the twentieth century, gas discharges were used as ion sources for first-generation mass spectrographs. In 1971 Coburn and Kay demonstrated the use of GD sources for the first time for the analysis of solids by MS, and in 1974 Harrison and Magee pioneered the development of what is considered modern analytical GDMS (glow discharge mass spectrometry). Approximately 10 years later, the first GDMS became commercially available as the VG

9000 (formerly VG Elemental), and the application of GDMS successfully evolved for the ultratrace elemental analysis of solids. It is estimated that over 100 of these instruments are still in service for this exact application.

GD devices are (mainly) low-pressure plasmas that generate atoms, ions, electrons, and photons when the application of voltage between two electrodes causes molecular breakdown of the gas medium. The ions in the GD maintain the plasma, but also allow for its use as an ionization source for MS analysis. GDs are versatile sources that can be used for sample atomization and ionization. Over the past 40 years, GDMS has been recognized as an analytical technique of choice for ultratrace element analysis in solid metal alloys and semiconductors. More recently, the capacity for the analysis of solution and gaseous phase samples has also been developed.

In MS analysis, the ions present in the discharge plasma are transported from the source area through a small orifice into an adjacent chamber that has a lower pressure that is adequate for the particular mass analyzer (**Figure 1**). Ions originated in the discharge plasma are sorted according to their mass-to-charge ratio (m/z), resulting in a mass spectrum that represents the composition of the sample of interest, which in all cases is the cathode electrode. The resulting spectrum provides isotopic abundance information, hence allowing the use of techniques such as isotope dilution. In GDMS studies, argon is the most common discharge gas used, and the typical discharge voltage and gas pressure are 1 kV and 1 Torr, respectively.

Figure 1 General schematic diagram of a GD source coupled to a mass spectrometer.

Glow Discharge Basics

Applying a high voltage across two electrodes in the presence of an inert gas causes the breakdown of the gaseous medium, resulting in electron-ion pairs and allowing current to flow between the electrodes. This type of current flow in a gas is considered a plasma. **Figure 2** represents the fundamental processes taking place in any GD source. The positive- and negative-charged species will flow toward the cathode and anode of the system, respectively. When ions with sufficient energy (> 30 eV) bombard the surface of the cathode, atoms will be ejected or 'sputtered' away from the surface of the cathode. This process of cathodic sputtering is responsible for atomizing the sample into the negative glow where a series of potential and kinetic energy transfers take place. Helium and argon are the typical gases used for GD sources due to their high metastable level energies (He, 20.6 and 19.8 eV; Ar, 17.7 and 11.5 eV) and ionization potentials (He, 24.5 eV; Ar, 15.8 eV). In practice, though, argon is the discharge gas of choice in solids analysis, as it provides a much higher sputtering yield. The inelastic collisions of metastable atoms, ions, and electrons with atoms that reach the negative glow region will result in the excitation and ionization of these atoms. The major mechanisms responsible for excitation and ionization are:

It must be made clear that these processes are dictated by kinetics, and not thermodynamics. The ions formed and photons released in the negative glow can be analyzed by MS and OES (optical emission spectroscopy), respectively. The rates and the extents of the fundamental kinetic processes that take place in the plasma are governed by the operating conditions and the physical configuration of the GD source.

Glow Discharge Geometries

The basic design of a GD source must include an anode and a cathode (which most commonly is the analytical sample). The most important aspect with a GD design is that the geometry allows for efficient sample interchange, reproducible sputtering, and effective ion production/extraction. The most common configurations found in the literature are the coaxial cathode, planar diode, Grimm-type, and hollow-cathode geometries (**Figure 3**). Typical operating conditions for the different geometries can be found in **Table 1**. The coaxial cathode (**Figure 3(a)**) is the most common configuration, found principally in commercial GDMS instruments. This configuration allows for pin-like or disc-shaped samples to be placed into the end of a direct insertion probe that acts as the

Figure 2 Fundamental processes occurring in a glow discharge plasma.

Figure 3 Diagrammatic representations of the various GD source configurations: (a) coaxial cathode, (b) planar diode, (c) Grimm-type source, (d) hollow-cathode lamp, (e) cylindrical hollow-cathode design, and (f) hollow-cathode plume.

Table 1 Operational conditions for glow discharge geometries

Geometries	Detection method	Operational conditions
Coaxial	MS	500–1000 V 5 mA 0.4–2.0 Torr Ar
Grimm type	MS and OES	500–1500 V ≤ 5 mA 1.0–6.0 Torr Ar
Hollow cathode	MS and OES	~ 400 V 10–100 mA ≤ 10 Torr Ar (or He)

cathode, whereas the source housing is the anode. The end of the samples is exposed to the discharge for sputtering, and the ions are sampled through an ion exit aperture to the mass analyzer region.

It may be difficult to form pin-like or disc-shaped samples in some cases. Therefore, the planar diode geometry (**Figure 3(b)**) was designed to analyze large flat samples. Note that this configuration is just a variation of the coaxial cathode design. The flat sample (cathode) is placed parallel to the anode in a closed cell. The housing is made up of the anode and the cathode mount, and the ions are introduced into the mass analyzer in the same manner as in the coaxial design. This geometry allows for depth profiling of the flat samples.

The next configuration of note is the Grimm-type source (**Figure 3(c)**), which is typically used for atomic emission spectroscopy, but can be used for MS as in the

case of the Thermo Element GD commercial instrument. This configuration is similar to the planar diode, but has an additional pumping system very close to the sample that prevents redeposition of sputtered atoms. The anode is placed less than one dark space from the cathode, resulting in a very stable, restricted discharge. Surface and depth-resolved analyses are possible due to the restricted GD, and the additional pumping system near the cathode results in operation at higher pressures than the other geometries.

The last geometry of importance is the hollow cathode. When two cathodes are located close to each other, their discharges will coalesce into one single negative glow region. This phenomenon makes the hollow cathode an attractive geometry due to the increased sensitivity that results from the increased sputtering and ionization rates in comparison to the previously mentioned configurations. The hollow-cathode lamp (**Figure 3(d)**) is the most common of the hollow-cathode configurations; it can be used as an ion or photon source. There is a cylindrical hollow-cathode design (**Figure 3(e)**) that allows for the sample to be introduced into the cavity and then atomized and excited/ionized. The last type is the hollow-cathode plume (**Figure 3(f)**), which allows for the sample to be placed at the end of a cylindrical tube with a small opening put into the middle of the sample, resulting in the plasma being pushed through the orifice.

Glow Discharge Operation Modes

GD sources can be operated by direct current (dc), radio frequency (RF), or pulsed power modes. The sample type, detection method, and conditions will dictate which method is used. The dc mode is the simplest of the three operational modes, and the most commonly used for MS. This mode creates a stable steady-state source of ions, which is easily amendable to any type of mass analyzer. Because the sample acts as the cathode in all of the configurations shown in **Figure 3**, only electrically conductive samples can be analyzed using the dc mode. Detection limits for conductive samples using the dc mode are typically found to be below 1 ng g^{-1} for high-resolution mass analyzers.

Not being able to analyze nonconductive samples led to the use of RF powering schemes that provide the ability to directly analyze nonconductive glass, ceramic, and polymer samples. When using RF powers (13.56 MHz), no charging takes place at the sample (cathode) because of the oscillation of positive and negative charges that bombard the 'cathode' and neutralize each other, so that the net charge is neutral. In the 1970s, Coburn and Kay as well as Harrison and coworkers published the first work with RF-GDMS sources. In 1989, Marcus and Duckworth began the main exploration into the use of the RF-GDMS as an analytical tool. RF power supplies cost somewhat more money than dc power supplies, but offer the advantage of analyzing nonconductors with similar detection limits compared to those of conducting samples with the dc mode.

Another operational mode that has been drawing a good deal of interest is the pulsed power mode. It operates by applying high short-term (millisecond) power (either RF or dc) to the cathode. This pulsed mode has improved sensitivity due to the enhanced sputtering that allows for increased analyte excitation and ionization. When operating a GD source with the pulsed mode, the discharge gas and analyte ions are created at different times. Thus, with the use of a time-gated detector, it is possible to have time-resolved detection, resulting in an improved signal-to-noise ratio and greater spectral simplicity, as background gas species are not observed.

Mass Analysis and Quantification

GD plasmas commonly operate between 0.1 and 10 Torr, whereas MS systems operate at a pressure of $\leq 10^{-5}$ Torr to prevent the collision of ions during their flight path or arcing due to high voltages. Therefore, the transport of ions from the plasma to the mass analyzers in GDMS instruments involves three vacuum regions: (1) the GD ionization source (~ 1 Torr), (2) the intermediate region ($\leq 10^{-4}$ Torr), and (3) the mass analyzer region ($\sim 10^{-6}$ Torr).

Since the 1970s, GD ion sources have been interfaced to all of the common mass analyzers, including magnetic sectors, quadrupole mass filters, quadrupole ion traps, time-of-flight (TOF) devices, and Fourier transform ion cyclotron resonance (FT-ICR) devices. Although the low-pressure GD plasma is sustained in a high-purity ($> 99.999\%$) argon discharge gas, there are instances of spectral interferences due to residual gases as well as isobaric elemental overlaps and the presence of dimers and argide species. For this reason, magnetic sector instruments have been by far the predominant analyzers in commercial systems. The first commercially available GDMS system employed a double-focusing analyzer and has been employed successfully for depth profiling and the analysis of metal alloys, semiconductors, powders, and nonconductors (with RF powering) with nominal resolution on the order of 4000 and parts-per-billion-level sensitivities. Another commercially available GDMS was the VG GloQuad (VG Elemental, Thermo group), which employed a quadrupole mass filter. **Table 2** includes a comparison of the mass analyzers used in GDMS, and **Figure 4** depicts a general schematic diagram of a GD quadrupole mass spectrometer system.

GD source interfacing to OES and MS instruments has been undertaken for the elemental analysis of bulk solid materials, as well as for depth profiling. The mass spectra obtained by GDMS allow for more simplistic interpretation of qualitative results when compared to the emission spectra because each element has fewer isotopes than optical transitions. Calibration curves and relative sensitivity factors (RSFs) are the two most common quantification methods used in GDMS, although well-defined calibration standards or reference materials are required as opposed to simple generation of calibration curves based on serial dilution of standard solutions. The experimental factors taken into account when performing any analysis by GDMS are sample (matrix) composition, sample positioning, discharge pressure and power, source configuration, ion sampling efficiency, and mass analyzer.

Use of the calibration curve method can be problematic in GDMS because of the many sources of irreproducibility (e.g., sample position) and the large number of elements targeted in a sample. Despite these facts, Grimm-type sources can provide accurate sample placement and create calibration curves with acceptable variability and linear response when using external standards. Overall, the number of materials available to be used as external standards is insufficient in many applications; therefore, internal standards are a virtual necessity for GDMS analysis. By using internal standards, matrix interferences and signal drift/deviation over time can also be compensated.

The second method used for GDMS quantification, based on the use of RSFs, was first developed for spark source MS. The RSF of an analyte element, x , is the ratio of its sensitivity (intensity, I , per unit concentration, C) to

Table 2 Comparison of mass analyzers for GDMS

Mass analyzer	Ion dispersion	Advantages	Disadvantages	Interface to GD
Sectors	Space	• Discriminate isobaric interferences • Commercially available (1980s)	• Complex and costly • Scan speed	1970s
Time-of-flight	Time	• Simple • Speed • Good resolution with reflection	• Complicated ion extraction	1990s
Quadrupole mass filter	Selective m/z transmission	• Scan speed • Peak hopping • Commercially available • Compact design • Low cost in comparison to magnetic sectors	• Limited resolution	1970s
Ion trap	Selective m/z ejection	• Remove polyatomic isobaric interferences using CID • Compact design • Less expensive than quadrupoles and magnetic sectors	• Ion admission from external sources	1990s
FT-ICR	Magnetic trapping and cyclotron frequency measurement	• High resolution resolves isobaric interferences • CID possible for the removal of polyatomic interferences	• Cost and complex • Limited dynamic range because of space charging effects • Ion admission from external sources	1980s

Note: CID, collision-induced dissociation.

**Figure 4** General schematic diagram of a GD quadrupole mass spectrometer.

the sensitivity of some reference element, r :

$$\text{RSF} = \frac{I_x/L_x}{I_r/C_r} \quad [1]$$

During the quantification of an unknown sample, RSFs are applied to the ion beam ratios. The ion beam ratio is the ratio of the isotope's ion current with respect to the

total ion current and represents the concentration of that isotope in the sample. For most of the elements across the periodic table, the RSF values are within one order of magnitude of each other and do not vary much between sample matrices that have the same general composition. Because RSFs are effectively based on the relative ionization efficiencies of the elements within a sample, the

variations in the materials' sputtering rates do not affect the RSF values. Therefore, GDMS has the ability to perform standardless semiquantitative analysis to achieve accuracies on the order of 20%. When higher accuracy quantitative analysis is required, RSFs based on matrix-matched standards do provide single-digit values.

GDMS Applications

The primary applications of GDMS over the decades have involved ultratrace elemental analysis of bulk metals and semiconductors, although nonconductors, thin films, solution phase samples, and gaseous phase samples have also been evaluated. **Table 3** shows a compilation of the many properties of GDMS observed over the years that have allowed its application in so many fields of material science. The following paragraphs will briefly describe the application of GDMS toward the analysis of the different samples mentioned earlier.

Bulk Metals

These types of samples are the most typical for dc-powered GDMS analysis due to the fact that sample preparation is very simple and spectra can be acquired within minutes. In most cases, the sample (e.g., high-purity metal or metal alloy) is cut or machined in a pin or disc form to serve as the cathode of the discharge plasma. In the case of magnetic sector instruments, the high ion beam currents ($\sim 10^{-9}$ A), high spectral resolution, and low detector background level yield extremely low limits

of detection (ng g^{-1}), not achieved in multielement analysis by any other solids analysis technique.

Semiconductors

Semiconductors can also be readily sputtered as the cathode in GDMS, even though they may display limited inherent conductivity. The electrical properties of semiconductor materials depend on the impurities present in the sample. Therefore, the use of GDMS as an ultratrace technique is important to manufacturers who need to precisely know the elemental composition values of impurities as well as dopants.

Nonconductors

The analysis of this type of sample was the impetus for the development of RF-GDMS. With the use of RF-GD sources, no charging takes place at the cathode, as the accumulated positive charges are neutralized because of electron bombardment during the positive half of the RF cycle. Alternatively, nonconducting samples have also been analyzed by dc GDMS using two different methods presented in the literature. The first approach involves mixing the nonconductive sample with a conducting host matrix (e.g., binding powder). This method is time consuming, and contaminants can be introduced during mixing. The second approach, which was first introduced by Hamilton and Hutton in 1993, uses a metallic diaphragm as a secondary (or sacrificial) cathode in front of the flat nonconductive surface. This method has been applied to many sample types (e.g., ceramics, glasses, polymers, marble, sediments, and particulate matter), although the overall efficiency is low. To be clear, the RF approach is applicable to situations where depth-resolved analyses are also required.

Thin Films

Although bulk metals analysis is the bread-and-butter application, GDMS is also a surface analysis technique. Surface analysis of thin metal films by GDMS demonstrates very clearly the process of GD sputtering, which leads to the erosion of the sample 'layer by layer' and gives rise to qualitative and quantitative depth profiles. As successive layers are sputtered from the surface and measured as a function of time, the elements' concentration as a function of sputtered depth can be derived. Most of the depth-profiling studies have been carried out using quadrupole mass filters, as their fast scanning capabilities can monitor the transient signals of multiple elements more effectively than magnetic sector instruments. In principle, a TOF mass analyzer is the ideal approach to performing high-fidelity depth profiles.

Table 3 Glow discharge mass spectrometry properties

<i>Advantages</i>	<i>Disadvantages</i>
• Simple and economical • Stable supply of ions characterizing the sample composition • Limits of detection in the ppb level • Uniform sensitivity for most elements • Inert discharge environment • MS spectra simpler than optical emission • Isotopic information • Minimal matrix effects • Fast qualitative scan of the periodic table • Uniform ion response for quantitative analysis using RSFs • Primarily no sample preparation • Analysis of metal and non-metal elements	• Differential pumping necessary due to the gas load • Spectral interferences (discharge gas and gas/matrix molecules) • Mainly use for solids • Low sample throughput • Few commercial vendors

Figure 5 LC-PB mass spectra of caffeine obtained with the (a) electron ionization and (b) GD ion sources, along with the (c) NIST library spectrum. (d) Chemical structure of caffeine.

Solution Phase Samples

Even though GDMS is considered a solid-state analytical technique, it has also been applied for the analysis of solution phase samples. Initially, the analysis of solution samples was carried out by drying the solution on the cathode and sputtering the dried solution residues when the discharge is initiated. Marcus and coworkers introduced the particle beam (PB) interface, coupled to a GD source for liquid chromatography (LC) separations and detection by either OES or MS. A review involving the PB/GD coupled to OES and MS systems has been published recently. This liquid chromatography particle beam mass spectrometry (LC-PB-MS) system, which uses interchangeable ionization sources (i.e., electron

impact and GD), has been employed for the chemical characterization of synthetic mixtures (e.g., selenoaminoacids and organic and inorganic arsenic) and real world samples such as botanical extracts. In all cases, detection limits in the nanogram level were acquired for both molecular and elemental species. **Figure 5** shows the LC-PB mass spectra for caffeine obtained using the electron impact and GD ion sources, as well as caffeine NIST mass spectra.

Gaseous Phase Samples

The very nature of a GD plasma is the ionization of the discharge gas, and so the use of a GD source for analysis

of a gaseous sample is a natural extension of the methodology. In 1988, McLuckey and coworkers created an atmospheric sampling GD source (i.e., using air as the discharge gas) for the analysis of trace impurities in air samples. In 1996, the same approach was used for the analysis of trace quantities of explosive vapors. However, it is important in environmental and toxicological areas to acquire atomic and molecular information about the sample of interest. With that in mind, in 1995, Giglio and Caruso developed an RF-GDMS for gas chromatography (GC)-MS analysis. Those studies demonstrated the ability to 'tune' the discharge conditions to affect different extents of analyte fragmentation. Subsequently, Hieftje and coworkers designed a dc gas-sampling GD to be placed on an ICP-TOF-MS. The GC-GDMS systems have been applied to halogenated compounds, organotin species, and fuel samples. Overall, the GC-GD mass spectra exhibit fragmentation patterns similar to those obtained from an electron ionization source, permitting NIST spectral library comparison.

Conclusion

It has long been demonstrated that GDMS is a powerful analytical tool for direct elemental analysis of bulk solids, and more recently gaseous and solution phase samples. The relative simplicity of the devices and ease of coupling to different mass analyzer geometries allows a certain amount of tailoring not available to other MS methods. Tuning of ion source designs and powering schemes to the applications at hand, although perhaps viewed as adding complication, provides the analyst with greater flexibility to attack a given problem. Perhaps the greatest limitation of the technique is, frankly, the lack of commercial interest versus the vast diversity of organic

MS manufacturers. This situation, of course, will only change by current user demand and the demonstration of the solving of important problems that, to date, have not been realized by current commercial systems.

The higher halogens, chlorine, bromine and iodine all possess NMR active nuclei, all of which are quadrupolar. Chlorine has two NMR active isotopes ^{35}Cl (75%) and ^{37}Cl (25%) of which ^{35}Cl is the isotope of choice owing to its higher magnetogyric ratio and natural abundance. Bromine also presents two NMR active isotopes ^{79}Br (50.5%) and ^{81}Br (49.5%). Despite its marginally lower natural abundance, ^{81}Br is the isotope of choice because of its slightly higher magnetogyric ratio. Iodine has only one NMR active nucleus ^{127}I (100%). More NMR studies have been reported on chlorine than on the other two halogens for two reasons: (i) the chloride ion is the most abundant intracellular anion in normal mammalian cells, giving a biological incentive for NMR studies and (ii) both isotopes of chlorine have relatively low quadrupole moments, reducing

unfavourable quadrupolar interactions and consequently providing enhanced visibility relative to the other halogens. This chapter reviews the use of NMR to study halides in biological systems, in solution chemistry and in solids. In particular it concentrates on the use of quadrupolar interactions from the isotopes available. There have been relatively few reviews of halogen NMR (excluding ^{19}F) and as a consequence several leading papers from the primary literature are included in the Further reading section list at the end of this article.

Nuclear Properties

The nuclear properties of the five NMR active isotopes of the halogens are presented in Table 1.

Quadrupolar Relaxation and Visibility

The NMR spectra of the halogens are dominated by the fact that all the isotopes are quadrupolar. Indeed, the majority of the reported studies of halogen NMR make use of the resulting quadrupolar interactions. Many of the problems that arise and solutions adopted are similar

Table 1 Nuclear properties of the halogens other than ^{19}F

Isotope	Spin	Natural abundance (%)	10^{-7} Magneto-gyric ratio γ ($\text{rad T}^{-1} \text{s}^{-1}$)	10^{28} Quadrupole moment Q (m^2)	NMR frequency Ξ (MHz)	Relative receptivity D^C
^{35}Cl	3/2	75.53	2.624	-8.2×10^{-2}	9.809	20.2
^{37}Cl	3/2	24.47	2.184	-6.5×10^{-2}	8.165	3.78
^{79}Br	3/2	50.54	6.726	0.33	25.140	2.28×10^2
^{81}Br	3/2	49.46	7.250	0.27	27.100	2.79×10^2
^{127}I	5/2	100	5.390	-0.79	20.146	5.41×10^2

Ξ is the observing frequency in a magnetic field in which ^1H is at 100 MHz.

D^C is the receptivity relative to ^{13}C .

Quadrupole moments Q are the least well-determined parameters in this table.

Data taken from Mason J (1987). In: Mason J (ed.) *Multinuclear NMR*, p. 623. New York: Plenum Press.

to those involved with the alkali metals. Quadrupolar nuclei have an asymmetric distribution of charge which gives rise to an electric quadrupole moment. Apart from when the nucleus is in an environment with cubic or higher symmetry, the quadrupole moment interacts with the electric field gradient (EFG) experienced by the nucleus, giving rise to, among other things, quadrupolar relaxation. The strength of the quadrupolar interaction between the quadrupole moment (eQ) and the electric field gradient (eq) is given by the quadrupolar coupling e^2qQ/b . This can take values from very small to hundreds of MHz depending on the magnitudes of Q and q .

In solution, modulation of the EFG at the quadrupolar nucleus by isotropic and sufficiently rapid molecular motions (where $\omega_0\tau_c \ll 1$) leads to relaxation according to the expression:

$$\frac{1}{T_1} = \left(\frac{3}{40}\right) [(2I+3)/I^2(2I-1)] (1 + \eta^2/3) e^2qQ/\hbar)^2 \tau_c$$

where η is the asymmetry parameter associated with the EFG.

For all of the nuclei in this chapter the quadrupolar couplings for covalently bound halogens are typically many tens of MHz, depending upon the particular case (~ 70 MHz for chloroalkanes). This can be thought of as arising from the asymmetric distribution of electrons in the covalent bond giving rise to a large EFG at the nucleus. For molecules in solution that tumble with typical correlation times (τ_c) of 10^{-12} s, this gives rise to T_1 and T_2 values that are typically in the submillisecond range. As a consequence, line widths range from the very broad to the invisibly broad with the latter case being the norm. With very broad line widths due to short T_2 values, much if not all of the halide resonance can be lost in the dead time between the pulse and the start of signal acquisition. Thus, quadrupolar relaxation has a devastating effect upon the signals of the covalently bonded halogen nuclei in solution, rendering them invisible in all but the most favourable circumstances. In passing, it is worth noting that the ^{35}Cl line width in a typical small molecule like CCl_4 is about 2000 ppm at an observing frequency of 10 MHz. This has to be compared with a chemical shift range of around 1000 ppm from aqueous Cl^- , which is amongst the most shielded cases, to ClO_4^- , which is one of the most deshielded cases.

Quadrupolar couplings are smaller in cases where chlorine is covalently bound to the second and third row elements such as silicon, phosphorus, sulfur and arsenic ($\text{Si-Cl} \sim 35$ MHz), making observation easier but the lines are still very broad.

The anions themselves in solution present a different picture since they are subject to much lower quadrupolar interactions. In aqueous solution the anions are solvated by hydrogen bonding. At any one instant the pattern of

hydrogen bonded water molecules around the anion does not have spherical symmetry but is always close to it. Thus the quadrupolar couplings are much lower than for the covalently bound halogens but are not zero. Typically, in aqueous solution and in the absence of extraneous influences, both isotopes of chlorine show Cl^- line widths of 10–15 Hz, both isotopes of bromine show Br^- line widths of ~ 400 Hz, $^{127}\text{I}^-$ has a line width of over 1000 Hz.

Covalent compounds with the halogen nucleus at a site of tetrahedral or octahedral symmetry, as in ClO_4^- or IF_6^+ , present a low EFG at the halogen nucleus and frequently have relatively sharp resonances. Indeed the spectra of the tetrahedral perhalate ions in acetonitrile solution show exceptionally sharp lines that enable secondary isotope effects on shielding to be observed. The shielding difference between $(\text{Cl}^{16}\text{O}_4)^-$ and $(\text{Cl}^{18}\text{O}^{16}\text{O}_3)^-$ is 0.090 ppm.

In cases where molecular motion is restricted ($\omega_0\tau_c$ is not $\ll 1$) the situation is more complex. The quadrupolar interaction with the nucleus shifts the energies of the Zeeman levels according to the square of the quantum number to a first approximation. Thus, the energy level splittings for a nucleus with $I=3/2$ (e.g. $^{35/37}\text{Cl}$ and $^{79/81}\text{Br}$) become as illustrated in **Figure 1**. With rapid isotropic motion, as described above, the multiple line pattern will collapse into a single line. In the absence of rapid isotropic motion the relaxation rate of the outer transitions, which combine to have 60% of the total

Figure 1 Changes in the energy levels for a spin 3/2 nucleus subject to a quadrupolar interaction.

intensity, is different from that of the inner transition which has 40% of the total intensity. The frequencies of the outer transitions also shift from the inner transition (dynamic frequency shift). There are three principal consequences of these changes for cases where the motion of halogen is restricted. Firstly, line shapes become a double and not a single Lorentzian, secondly two relaxation times are apparent, and finally, where the more rapid relaxation time becomes very short, partial or total invisibility of the signal from the outer transitions may occur. For example, studies on dog erythrocytes showed a relatively sharp ^{35}Cl line (line width ~ 40 Hz) but only 40% visibility and in renal tubules the ^{35}Cl signal was reported to be invisible. An excellent review of quadrupolar relaxation effects has been given by Springer (listed in the Further Reading).

In solids the situation is even more complex with, for example, the possibility of multiple quantum relaxation pathways. A discussion of this is beyond the scope of this article. In general, however, relaxation times for halogens in solids are several orders of magnitude longer than for those in solution and this, in turn, in favourable cases, does allow effects due to the halogen nuclei to be observed.

Biological Chloride

Chlorine is the eighth most abundant element in the human body. Although it is present in large amounts as chloride ion in extracellular spaces, the intracellular concentration of chloride is high and it is the most abundant intracellular anion in normal mammalian cells. For example, its concentration in the human erythrocyte is ~ 150 mM. Chloride is involved in many important biochemical pathways. The most used membrane transport system in mammals is band III protein whose role is to exchange HCO_3^- inside the cell for Cl^- outside, thus facilitating the removal of CO_2 . Abnormal chloride transport is implicated in several serious medical conditions such as cystic fibrosis and Duchenne muscular dystrophy. Many good reasons exist, therefore, to develop NMR methods to study biological chloride.

One of the main problems in using NMR to study biological chloride is that the chemical shift of aqueous $^{35}\text{Cl}^-$ is essentially independent of the ion's surroundings, making differentiation of intra- and extracellular chloride difficult. Further difficulties arise because of the binding of chloride to proteins, some of which may contain paramagnetic ions, which can greatly increase the line width. If the exchange rate between the free and the bound chloride is slow, this leads to a loss of signal.

The first problem can be met by using a contrast reagent (either a shift or a relaxation agent) in one of the compartments, normally extracellular. Aqueous shift reagents that have been employed include Co(II) either as

Co^{2+} cations or as the triglycinate complex $[\text{Co}(\text{Gly})_3]^-$. Manganese(II) has been shown to be an extremely efficient relaxation agent for $^{35}\text{Cl}^-$ in which rapid exchange of chloride for water in the inner ligation sphere brings the chloride ions transiently under the paramagnetic influence of the five unpaired electrons on the manganese.

It has been argued that the relaxation agent Mn^{2+} is superior to Co(II) -based shift reagents. First, the concentrations of Co(II) reagents needed to visualize intracellular or intravesicular chloride are considerably higher than those of Mn^{2+} . Second, all contrast reagents induce paramagnetic line broadening of the extracellular ^{35}Cl resonance that is proportional to the square of the magnetic field whilst the induced shift is only linearly dependent on the field. Therefore, on moving to the high fields required to attain satisfactory signal-to-noise, Mn^{2+} has the advantage of requiring even lower amounts of reagent to achieve the same line widths, whilst Co(II) -based shift reagents require even higher concentrations to achieve the same relative separation of resonances.

Cobalt(II) as a shift reagent has been employed to visualize the $^{35}\text{Cl}^-$ resonance from chloride ions inside vesicles and erythrocyte ghosts. The latter observation allowed measurements of the kinetics of chloride/sulfate exchange mediated by the band III protein. The same group also used Co(II) to observe Cl^- inside the cells of an alga, *Chlorella pyrenoidosa* and inside the cells of a suspension of cultured plant cells from *Nicotiana tabacum*. In both of these cases relatively sharp intracellular resonances that were suitably separated from the extracellular resonance were observed.

For many years it was believed that the $^{35}\text{Cl}^-$ resonance from chloride ions inside human erythrocytes was invisible owing to interaction of the ions with the protein haemoglobin that is paramagnetic in its deoxy state. However, the shift reagent $[\text{Co}(\text{Gly})_3]^-$ and the relaxation agent Mn^{2+} have been used in separate studies that demonstrate the visibility of the intracellular chloride as a line that is ~ 700 Hz wide (11.75 T magnet). The intracellular $^{35}\text{Cl}^-$ resonance shows a double Lorentzian line shape and two T_2 values of ~ 0.09 and 1.2 ms, in keeping with a halide ion undergoing restricted motion. **Figure 2** shows typical spectra using both shift and relaxation agents. In the report using the shift reagent the exchange of intracellular Cl^- with extracellular hypophosphite (H_2PO_2^-) as a typical monovalent anion was followed by ^{35}Cl NMR. The exchange followed first order kinetics with a rate constant of $2.4 \pm 0.8 \times 10^{-3} \text{ min}^{-1}$. This work shows the potential of ^{35}Cl NMR to study chloride transport kinetics in cellular systems such as erythrocytes.

Manganese(II) has been used in conjunction with model vesicle systems to examine membrane transport induced by natural and synthetic anion carriers.

There are problems, however, with the use of Co^{2+} and Mn^{2+} as contrast reagents because it has been shown

Figure 2 The ^{35}Cl NMR spectra at the mid-points of data accumulation (1) 20, (2) 60, (3) 100, (4) 140 and (5) 180 minutes of human erythrocyte suspensions at 70% haematocrit containing (a) 60 mM $[\text{Co}(\text{Gly})_3]^-$, 40 mM CoCl_2 (b) and 20 mM MnCl_2^- (c). The symbols i and o denote the resonances originating from the intra- and extracellular halide, respectively. From Lin W and Mota de Freitas D (1996) *Magnetic Resonance in Chemistry* 34: 768–772. Copyright John Wiley & Sons Limited. Reproduced with permission.

that biological membranes are very slowly permeable to these ions. It is, however, claimed that the shift reagent $[\text{Co}(\text{Gly})_3]^-$ does not show membrane permeability and is, therefore, more suitable for studies on model systems.

The other way that ^{35}Cl NMR can be used in biological systems is in the study of chloride bound to proteins or other macromolecules. Sometimes this can be done by direct visualization of the resonance or from its free induction decay. More commonly it is performed by relaxation time measurements provided that there is rapid exchange of bound and free anions, because bound chloride relaxes very much more rapidly than free chloride. Frequently, double quantum filtered (DQF) spectra are employed which give useful information on chlorine bound to sites on the macromolecule.

The most studied system has undoubtedly been the integral membrane band III protein which mediates the one-for-one exchange of hydrogencarbonate and chloride ions across the membrane, thus playing an integral part in respiration. NMR proved useful in verifying a ping-pong mechanism for the mode of action of this protein. Binding sites for chloride at both surfaces have been identified although the cytoplasmic face has the larger number. Chloride affinities for the binding sites determined by NMR, DQF spectra and $^{35}\text{Cl}^-$ and $^{37}\text{Cl}^-$ relaxation rates at a variety of field strengths, both in absence and presence of various inhibitors, have also given large amounts of information about the operation of this important protein.

In a typical example, DQF ^{35}Cl NMR was used to study the binding of Cl^- to external sites on the surface of red blood cells. A DQF ^{35}Cl signal was observed in cell suspensions containing 150 mM KCl, but the DQF signal was totally eliminated by adding 500 μM

4,4'-dinitrostilbene-2,2'-disulfonate (DNDS), an inhibitor that interferes with Cl^- binding to the band III protein transport site. This result shows that only the binding of Cl^- to transport sites of band III can give rise to a ^{35}Cl DQF signal from red blood cell suspensions. In accordance with this concept, analysis of the single quantum FID revealed that signals from buffer and DNDS-treated cells could be fitted with a single exponential function, whereas the FID signals of untreated control cells were biexponential. The band III-dependent DQF signal is thus caused, at least in part, by non-isotropic motions of Cl^- in the transport site, resulting in incompletely averaged quadrupolar couplings.

Other biological systems that have been investigated by such techniques include sarcoplasmic reticulum membranes, superoxide dismutase, dromedary haemoglobin, the oxygen-evolving complex of spinach photosystem II, the zinc binding sites of human α -2-macroglobulin, alkaline phosphatase and halorhodopsin chromoprotein.

Spin-Spin Coupling

The rapid quadrupolar relaxation of halogens, in general, effectively masks fine structure arising from scalar coupling between the halogen and other covalently bound magnetically active nuclei. Exceptions occur when the halogen experiences a low EFG as, for example, when it is bound in sites of high symmetry. Thus, for the octahedral IF_6^+ ion, the ^{19}F resonance appears as a sextet due to coupling to the ^{127}I nucleus ($I = 5/2$). Analogously, the ^{19}F spectrum of BrF_6^+ appears as two quartets due to coupling to the two almost equally populated Br isotopes (for both of which $I = 3/2$). In the perchlorate ions

Figure 3 ^{127}I spectrum (50.05 MHz) of 0.1 M $^{17,18}\text{O}$ -enriched $\text{Et}_4\text{NIO}_4^-$ in CH_3CN at 24°C . The central line arises from $^{16}\text{O}^{16}\text{O}_4^-$ (46%) and $^{18}\text{O}^{16}\text{O}_3^-$ (17%); the sextet arises from $^{17}\text{O}^{16}\text{O}_3^-$ (29%) and $^{17}\text{O}^{18}\text{O}^{16}\text{O}_2^-$ (6%). The vertical expansion reveals the slight variation in line widths of the sextet. From Dove MFA, Sanders JCP, and Appelman EH (1995) Comparative multinuclear (^{35}Cl , ^{79}Br , ^{81}Br , ^{127}I and ^{17}O) magnetic resonance study of the perhalate anions XO_4^- ($\text{X}=\text{Cl}$, Br or I). *Magnetic Resonance in Chemistry* 33; 44–58. Copyright John Wiley & Sons Limited. Reproduced with permission.

XO_4^- , when labelled with ^{17}O , it is possible to measure coupling between the halogen and the oxygen. **Figure 3** shows the ^{127}I spectrum of singly ^{17}O -labelled IO_4^- . The six lines arising from coupling between the ^{127}I and the ^{17}O are visible. For non-symmetric sites where direct determination of coupling constants is difficult it is sometimes possible to make use of the scalar contribution to the relaxation of a dipolar nucleus ($I=1/2$) coupled to the quadrupolar halogen. Typical values of one-bond J couplings to Cl , Br and I are given in **Table 2**.

Residual Dipolar Coupling in Solids

In the solid state the relaxation times of quadrupolar nuclei are typically several orders of magnitude greater than in solution. One important consequence of these

Table 2 Illustrative values of one-bond coupling constants to Cl , Br and I

Compound	Spin-spin coupling constant (Hz)
HCl	$J(^{35}\text{Cl}-^1\text{H}) = 41 \pm 2$

BrO_4^-	$J(^{79}\text{Br}-^{17}\text{O}) = 408 \pm 6$
BrO_4^-	$J(^{81}\text{Br}-^{17}\text{O}) = 440 \pm 6$
IO_4^-	$J(^{127}\text{I}-^{17}\text{O}) = 489 \pm 6$

longer relaxation times is the ability, sometimes, to determine indirect spin-spin coupling constants, J , involving quadrupolar nuclei. These experiments are performed typically by high resolution cross-polarization magic-angle spinning experiments on spin $1/2$ nuclei that are coupled to the quadrupolar nucleus. The longer quadrupolar relaxation times in solids mean that direct dipolar interactions involving quadrupolar nuclei are not completely averaged by the MAS. This is because the magnetic moments of the quadrupolar nuclei are quantized, not only by the magnetic field, B_0 but also by interaction with the electric field gradient tensor. Consequently the magic angle (described by the familiar $3\cos^2\theta - 1 = 0$) is no longer magic and fails to reduce the dipolar interaction to 0. Only since 1993 have examples of residual dipolar coupling of chlorine nuclei to ^{13}C been reported but many examples are now known. The residual dipolar couplings of chlorine to directly bonded ^{13}C are of the order of several hundred Hz and are field dependent, the coupling decreasing with increasing magnetic field. The observed ^{13}C doublets contain overlapping components from coupling of both ^{35}Cl and ^{37}Cl to the ^{13}C nucleus. Analogous residual dipolar coupling between $^{79/81}\text{Br}$ and ^{13}C has been observed in 1,4-dibromobenzene and 4-bromo-3,5-dimethylpyrazole.

Shielding

From a consideration of the section above on quadrupolar relaxation of covalent compounds it will be realized that, in all but exceptional cases, the large line widths of the resonances give rise to a low precision in the determination of chemical shifts for Cl , whilst shielding studies for Br and I are virtually impossible. Only in molecules in which the halogen is present in a

site of high symmetry can chemical shifts (relative to the free halide ion in aqueous solution as standard) be determined with precision. In the case of halogens present in non-ligated anions the chemical shift generally has a low dependence on the accompanying cation. Ligation can, however, have a substantial effect upon the chemical shift (see below). The largest deshieldings, relative to Cl^- , are to be found in species such as ClO_3F (978.1 ppm) and ClO_4^- (1002.5 ppm). The corresponding aqueous shifts for perbromate and periodate are 2478 and 4089 ppm, respectively. The normal chemical shift reference for halogen NMR is the frequency of the aqueous halide ion. Differences in the chemical environment of halogens are generally far more readily studied by using relaxation methods than by looking for chemical shift differences.

Halide-Ligand Interactions

Halide ions may be chelated by ligands that contain suitable arrays of hydrogen-bonding N–H groups. The binding is stronger if the NH is present as part of a positively charged ammonium ion. The ligands (shown as [1] and [2]) form tetra- and hexaammonium ions, respectively, and bind a halide strongly inside the cavity with hydrogen bonds pointing inwards. The chelation of halide ions by ligands of this type is demonstrated by the generation of very substantial chemical shifts for the halide ions either as the ligand is added to an aqueous solution, or as the pH of the solution is lowered to generate the ammonium ion centres. Line widths of the encapsulated $^{35}\text{Cl}^-$ ions range from tens to thousands of Hz, depending upon the particular case. The larger line widths demonstrate that there are appreciable electric field gradients present at the chloride nucleus due to transient deformations of the coordination sphere away from ideal symmetry.

Figure 4 illustrates the use of ^{35}Cl NMR to study the binding of chloride ions to the ligand [1] (as the 4H^+ species) as the ratio of free to bound Cl^- is increased. The chloride ion enters the centre of the ligand and is held in position by four inward facing hydrogen bonds from the $\text{N}^+\text{--H}$ groups. The signal near 50 ppm is from the coordinated $^{35}\text{Cl}^-$ and is relatively sharp owing to the tetrahedral site symmetry. The signal at 0 ppm is from free $^{35}\text{Cl}^-$, which at relatively small amounts of free Cl^- is 300 Hz wide due principally to dynamic line broadening that arises from exchange with the bound Cl^- . At an equal concentration of bound and free Cl^- the contributions to the line width of the free $^{35}\text{Cl}^-$ of 80 Hz are 36 Hz from exchange and 44 Hz from quadrupolar interactions. At higher relative concentrations of free Cl^- the exchange contribution to the line width diminishes still further but the free $^{35}\text{Cl}^-$ line remains relatively

broad probably owing to attraction of the free Cl^- ions to the exterior of the triply positively charged complex.

[1]

[2]

A = $-\text{CH}_2-\text{CH}_2-$

B = $-(\text{CH}_2)_2-\text{O}-(\text{CH}_2)_2-$

Halide ions show a weak association with cyclodextrins which can be visualized by the quadrupolar line broadening of the halide resonances. Competition between bromide ions and other ions for the binding site in cyclodextrins can be studied by the reduction in the $^{81}\text{Br}^-$ line width as other electrolytes are added to an aqueous solution containing cyclodextrin and KBr.

Halide-Cation Interactions

Interaction between ions of opposite charge is an important aspect of the chemistry of electrolyte solutions. The line widths of quadrupolar nuclei are an important probe of such interactions since the closer two ions of opposite charge approach the greater the EFG at their nuclei. This in turn can lead to a stronger quadrupole interaction, more rapid quadrupolar relaxation and larger line widths. Thus studies of the concentration dependence of quadrupolar relaxation are probes for ionic

Figure 4 ^{35}Cl NMR spectra (at 39.2 MHz) of aqueous solutions of the Cl^- complex of ligand $[1]\cdot 4\text{H}^+$ (20 mM) and uncomplexed Cl^- as a function of the ratio of free Cl^- to Cl^- complex. The shifts are given in ppm relative to external aqueous NaCl (0.1 M); pH 1.5 and 20°C . Reprinted with permission from Kintzinger JP, Lehn J-M, Kauffmann E, Dye JL, and Popov AI (1983) Anion co-ordination chemistry – ^{35}Cl NMR studies of chloride anion cryptates. *Journal of the American Chemical Society* 105: 7549–7553. Copyright 1983 American Chemical Society.

interactions. Such concentration dependence varies markedly with the cation present. Most monovalent ions show a low dependence of quadrupolar relaxation with concentration but this is not the case with alkyl substituted ammonium ions. In one typical such study ^{35}Cl , ^{81}Br and ^{127}I NMR was used to study the interaction of halide ions with alkylammonium ions. The intrinsic line widths (line width at 1/2 height corrected for temperature and viscosity) of the halide ions, plotted against molality (m) of the salt, show distinct plateau in the region 1–4 m with the effect being greatest for iodide. These findings suggest the presence of contact ion pairs in these concentration ranges.

Similarly, the T_2 values of $^{35}\text{Cl}^-$ ions show a pH dependence in the presence of polybasic molecules such as polyamines, or amino acids such as histidine or arginine. The relaxation rates increase as the pH is lowered

and show steepest changes at pH values equivalent to the pK_a values for the various titratable groups. This is consistent with increasing ionic interactions between the anion as the number of positive charges on the organic substrate is increased.

Halogens in Conducting and Semiconducting Lattices

The ionic mobility of halogen-containing ions in solids, polymeric matrices and solutions may be studied by halogen NMR techniques. The self-diffusion of perchlorate ions in aqueous solutions of NaClO_4 , LiClO_4 and $\text{Mg}(\text{ClO}_4)_2$ has been studied using pulsed field gradient techniques.

Both ^{81}Br and ^{35}Cl MAS NMR have been used in the investigation of sodium, silver and halo-sodalite semiconductor supralattices. Useful information is available on the environments of the encapsulated clusters within the sodalite lattice. The Na_4X ($\text{X} = \text{Cl}, \text{Br}$) tetrahedra provide a symmetric environment around the halide and give rise to narrow resonances for specific locations. The spectra are sensitive to the distribution of anion empty cavities or to I^- -containing cavities.

^{35}Cl and $^{79\&81}\text{Br}$ T_1 measurements between 77 and 700 K shed light on ionic transport in (solid) silver halides. A hopping process due to thermally activated diffusion of defects accounts for the data. The chloride ion conductor $\text{CH}_3\text{NH}_3\text{GeCl}_3$ has a variety of solid state phases and shows electrical conductivity above 398 K. The mobile ion in the high temperature phase was deduced to be Cl^- because a disordered perovskite structure at the Cl site was found by Rietveld analysis of X-ray powder data and confirmed by ^{35}Cl NMR. At temperatures above 364 K a ^{35}Cl resonance becomes visible. This suggests that the rate of isotropic motion at the Cl^- site is becoming comparable with or greater than the quadrupolar coupling, thus reducing the importance of the quadrupolar interactions.

Two-Dimensional Spectroscopy

Two-dimensional multiple-quantum (2D2Q) ^{35}Cl NMR spectra of systems exhibiting electric quadrupolar effects have been obtained. In such spectra the single quantum spectrum is displayed along one axis against the double quantum spectrum along the other. Such spectra give information about the quadrupolar interactions present in ordered systems.

P_u	p orbital valence imbalance
$P_{m,n}$	transition probabilities
q	electric field gradient
Q	nuclear quadrupole moment
r	electron–nucleus distance
T	temperature
T_1	spin–lattice relaxation time
T_2	spin–spin relaxation time
δ	chemical shift
ΔE	mean excitation energy
$\Delta\nu_{1/2}$	line width at half-height
η	electric field gradient asymmetry parameter
σ	viscosity
σ	shielding parameter
τ_c	rotational correlation time
ω	angular frequency

All the elements of group 15 of the periodic table have at least one isotope suitable for study by NMR spectroscopy. The magnetically active isotopes of arsenic, antimony and bismuth (^{75}As , $I = 3/2$; ^{121}Sb , $I = 5/2$; ^{123}Sb , $I = 7/2$; ^{209}Bi , $I = 9/2$;) have high abundance and relatively high sensitivity; nevertheless they have been little employed in multinuclear NMR spectroscopy owing to their high spin quantum numbers, which produce large quadrupolar moments. In fact, an efficient quadrupolar mechanism dominates their relaxation behaviour and gives rise to extremely broad resonances; this has limited the application of ^{75}As , $^{121,123}\text{Sb}$ and ^{209}Bi NMR spectroscopy to species having a high degree of symmetry. Only a few NMR studies have been reported, and only a small amount of data, often useful in the determination of the molecular structure, is currently available.

Properties of the Nuclei

^{75}As is 100% abundant with a receptivity of 2.5×10^{-2} relative to the proton; ^{121}Sb is 57% abundant with a receptivity of 9.2×10^{-2} ; and ^{209}Bi is 100% abundant with a receptivity of 0.14×10^{-2} ; by contrast, ^{123}Sb is about 43% abundant with a receptivity of 1.9×10^{-2} . In the case of antimony, the nuclide generally chosen for NMR determinations is ^{121}Sb , presumably owing to the lower abundance of ^{123}Sb .

The group 15 nuclides can be studied by NMR spectroscopy only when the E-containing compounds ($E = \text{As, Sb, Bi}$) are highly symmetric, with E in the oxidation state +5. These nuclides are spectroscopically silent in nonsymmetric compounds or in the +3 oxidation state. Narrow line widths arise from quadrupolar nuclei residing at the centre of a highly symmetric ligand environment. In addition, in oxidation state +5, no lone pairs remain in the valence shell and tetrahedral or octahedral symmetry can be achieved through bonding of four or six donor ligands, as in the case of $(\text{SbCl}_4)^+$ and $(\text{SbCl}_6)^-$. By contrast, when the group 15 elements are in oxidation state +3, there is a lone pair in the valence shell and the structures are generally characterized by substantial electric field gradients at the central atom, which prevents observation of NMR resonances.

The main nuclear properties of group 15 nuclides are shown in Table 1.

Experimental Aspects

^{75}As , ^{121}Sb , ^{123}Sb and ^{209}Bi NMR spectra can be obtained efficiently using a broadband probe. The observation frequencies are 85.637 MHz (^{75}As), 119.696 MHz (^{121}Sb), 64.819 MHz (^{123}Sb) and 80.381 MHz (^{209}Bi) when ^1H NMR is at 500 MHz. The ideal spectral width setting is 20 kHz, to yield a data point resolution of 4.9 Hz per data point and an acquisition time of 0.205 s. The number of transients that must be accumulated varies with the nuclide under observation and with the concentration of the sample; however, typical values are 14 000 (^{75}As), 7000 (^{121}Sb), 36 000 (^{123}Sb) and 200 000–400 000 (^{209}Bi). A suitable line-broadening parameter can be applied by the exponential multiplication of the free induction decay prior to Fourier transformation. A line-broadening factor

Table 1 Selected nuclear properties of magnetically active isotopes of As, Sb and Bi

Receptivity relative to ¹ H	2.5 × 10 ⁻²	9.2 × 10 ⁻²	1.9 × 10 ⁻²	0.14

equal to the original line width will produce the optimum signal-to-noise ratio.

The chemical shift standards generally used (at room temperature) are 0.1 M [(Et₄N)⁺(AsF₆)⁻] in CH₃CN for ⁷⁵As, 0.3 M [(Et₄N)⁺(SbCl₆)⁻] in CH₃CN for ^{121,123}Sb, and a saturated solution of [(Me₄N)⁺(BiF₆)⁻] in CH₃CN for ²⁰⁹Bi. In some cases, 0.1 M [(Et₄N)⁺(SbF₆)⁻] in CH₃CN as standard (0.0 ppm) for antimony has also been used. All the antimony data reported here are referred to [(Et₄N)⁺(SbCl₆)⁻] at 0 ppm.

Chemical Shifts

⁷⁵As, ^{121,123}Sb and ²⁰⁹Bi chemical shift ranges are very large (Table 2 and Table 3). A positive sign indicates a chemical shift to higher frequency (lower shielding) with respect to the reference compound.

In the case of arsenic(+5) derivatives, the chemical shift range spans approximately 700 ppm, with the tetrahedral oxoanion (AsO₄)³⁻ and the cation (AsH₄)⁺ occupying the deshielded and the shielded ends of the range, respectively.

Although there is limited chemical shift data in the case of ⁷⁵As and ¹²¹Sb, it is possible to observe some general patterns analogous to those found for other nuclides, such as group 14 elements. For example, even if there seems to be no regularity among the shifts of the AsR₄⁺ compounds, the ordering in terms of alkyl substituent is consistent with that found for group 14 and group 15 alkyls: labelling the atoms of the structural unit [As(alkyl)₄]⁺ as As_α - C_β - C_γ - C_δ, methyl substitution for one hydrogen at the β position (Δβ) deshields by 11 ppm, Δγ shields by 5 ppm, and Δδ shields by 1 ppm. This trend in shielding effect as one proceeds down the chain is characteristic of methyl substitution.

In (AsF_{6-n}Cl_n)⁻ (*n* = 0–6) derivatives, the trend observed for F/Cl exchange in ⁷⁵As chemical shift also suggests an increasing shielding with increasing *n*, owing to lower electronegativity of chloride with respect to fluoride donor ligands; a further example is the difference in chemical shift for (AsF₅Cl)⁻ (12.2 ppm) and (AsF₅Br)⁻ (102.5 ppm).

In the case of the two heteropoly anions (AsW₁₂O₄₀)³⁻ and (AsMo₁₂O₄₀)³⁻ ('Keggin' anions), the chemical shifts reflect the influence of electron density surrounding the arsenic atom, which is dependent on the nature of peripheral metal atoms: as expected, the As atom will be shielded to a greater degree in the former anion than in the latter, the same trend being observed for phosphate anions. Moreover, both arsenic-containing heteropoly anions display chemical shifts that are upfield from the relatively deshielded arsenate ion (AsO₄)³⁻.

The antimony(+5) chemical shift range spans approximately 3500 ppm. Rather more information is available for ¹²¹Sb than for ⁷⁵As NMR chemical shifts. To date, (SbS₄)³⁻ and (SbBr₆)⁻ occupy the deshielded and shielded ends of the range, respectively.

In (SbF₆)⁻ and (SbCl₆)⁻ the small difference between the antimony shifts (~87 ppm) compared with those for analogous ³¹P and ⁷⁵As species (152 and 392 ppm, respectively) is probably due to the electronic excitation energy that in both antimony and, more likely, arsenic is responsible for the anomalous paramagnetic shielding term.

¹²¹Sb chemical shifts fall into the normal halogen dependence category and, in the case of the mixed halide compounds (SbX_nY_{6-n})⁻, it is possible to assign the *cis* and *trans* isomers by the pairwise additivity parameter, calculated using eqn [1]:

$$\delta_{\text{calc}} = \frac{n}{6} \delta_{\text{SbCl}_6^-} + \frac{6-n}{6} \delta_{\text{SbBr}_6^-} \quad [1]$$

The dominant contribution to the shielding, σ_p , can be expressed in the form

$$\sigma_p = - \left(\frac{2e^2 \hbar^2}{3\Delta mc^2} \right) \left(\left\langle \frac{1}{r^3} \right\rangle_p P_u + \left\langle \frac{1}{r^3} \right\rangle_d D_u \right) \quad [2]$$

The large variation in Sb shielding arises from the dominant and negative paramagnetic shielding term, σ_p . The magnitude of σ_p is directly proportional to changes in the inverse mean excitation energy (ΔE^{-1}), the mean inverse cubes of the p and d electron-nucleus distances ($\langle r^{-3} \rangle_{np}$ and $\langle r^{-3} \rangle_{nd}$), and the valence imbalance in the p and d orbitals centred on the Sb atom (*P_u* and *D_u*).

The relative chemical shifts of the SbX_4^+ and SbX_6^- ions follow the valence imbalance terms and are dependent upon the electron density and relative electronegativities of the halogens. The electronegativity difference of chlorine and bromine accounts quantitatively for the high-frequency shifts of $(\text{SbCl}_4)^+$ (847.0 ppm) and $(\text{SbCl}_6)^-$ (0.0 ppm) relative to those of $(\text{SbBr}_4)^+$ (95.3 ppm) and $(\text{SbBr}_6)^-$ (-2430 ppm), and the formal positive charge, which is expected to reside mainly on the Sb atom, accounts for the high-frequency shift of the $(\text{SbX}_4)^+$ cations compared to the $(\text{SbX}_6)^-$ anions, which have their formal negative charge located on the halogens.

Only one value is reported for antimony compounds having a symmetry other than octahedral or tetrahedral: SbCl_5 resonates at +509 ppm, but the line width is about 8000 Hz. This very broad absorption band illustrates the effect of the rate of quadrupolar relaxation as the geometry around the antimony nucleus is reduced from O_h or T_d to trigonal bipyramidal (C_{3v}).

In the case of the heaviest bismuth nuclide, only a few ^{209}Bi NMR data are available yet. For example, taking $(\text{BiF}_6)^-$ (0.0 ppm, 2700 Hz $^1J(^{209}\text{Bi}-^{19}\text{F})$) as reference, the anion $[\text{Bi}(\text{OTeF}_5)_6]^-$ is shifted to +126.7 ppm (2269 Hz $^1J(^{209}\text{Bi}-^{125}\text{Te})$) (Figure 1), contrary to what is observed in analogous $[\text{As}(\text{OTeF}_5)_6]^-$ and $[\text{Sb}(\text{OTeF}_5)_6]^-$ compounds, which exhibit low frequencies with respect to $(\text{AsF}_6)^-$ (Figure 2) and $(\text{SbF}_6)^-$, respectively. This anomalous behaviour could be caused by relativistic effects of the bismuth atom.

Coupling Constants

In the case of ^{75}As , only one $J(^{75}\text{As}-^1\text{H})$ (555 Hz) value, related to the $(\text{AsH}_4)^+$ cation, has been reported, whereas several $^1J(^{75}\text{As}-^{19}\text{F})$ values have been obtained from the spectra of $(\text{AsF}_n\text{Cl}_{6-n})^-$ derivatives, and these range from 897 to 1259 Hz depending on the position of the fluorine atom in the octahedron around arsenic. More recently, several $J(^{75}\text{As}-^{125}\text{Te})$ values have been measured (420–430 Hz) in $[\text{As}(\text{OTeF}_5)_6]^-$ compounds.

Also in $[\text{SbF}_n\text{Cl}_{6-n}]^-$ compounds, some $^1J(^{121}\text{Sb}-^{19}\text{F})$ values have been observed (Figure 3): the typical range is

1859–208 8 Hz and, as with arsenic, the values depend on the fluorine position around the antimony atom.

Relaxation Behaviour

For a quadrupolar nucleus, the relaxation under conditions of extreme narrowing can be described by

$$\Delta\nu_{1/2} = \frac{1}{\pi T_2} = \frac{1}{\pi T_1} = \frac{3\pi}{10} \left(\frac{2I+3}{I^2(2I-1)} \right) \times \left(\frac{e^2 q Q}{b} \right)^2 \left(1 + \frac{\eta^2}{3} \right) \tau_c \quad [3]$$

where $\Delta\nu_{1/2}$ is the line width at half-height, T_2 is the spin–spin relaxation time, T_1 is the spin–lattice relaxation time, I is the nuclear spin quantum number, e is the charge on the electron, Q is the nuclear quadrupole moment, q is the electric field gradient (EFG) along the principal z axis, η is the symmetry parameter for the EFG, and finally τ_c is the rotational correlation time.

A careful inspection of several factors in eqn [3] reveals that line widths are dramatically reduced for nuclides having a high value of I or a small value of Q , or both. Moreover, τ_c serves to increase the $\Delta\nu_{1/2}$ of the quadrupolar anion with increasing ionic/molecular radius, increased ion pairing and increasing solvent viscosity (decreasing temperature).

The resonance line widths for $(\text{MF}_{6-n}\text{X}_n)^-$ increase as n increases from 0 to 5 (with the exception of $(\text{SbF})^-\text{Cl}_5$), and are also greater for $\text{X} = \text{Br}$ than for $\text{X} = \text{Cl}$. This behaviour reflects the increase in the quadrupolar relaxation rate of the central nucleus as its octahedral environment is distorted by the replacement of F by the larger halogens. An analogous behaviour has been noted in the bromo-chloroantimonates(+5).

Although the larger radius of the $(\text{SbBr}_4)^+$ cation should result in a longer τ_c and larger $\Delta\nu_{1/2}$ values than for $(\text{SbCl}_4)^+$, the opposite effect is found; this is attributed to the greater Lewis acidity of the latter cation, which is expected to form with the very weakly basic SO_2ClF solvent a stronger, albeit weak, donor–acceptor bond than $(\text{SbBr}_4)^+$. An equilibrium concentration of the adduct leads to an increase in the EFG at the antimony nucleus and increased τ_c , both of which serve to decrease the relaxation time and increase $\Delta\nu_{1/2}$.

A more complete study of the factors influencing relaxation behaviour has been made on arsonium salts by altering the alkyl group, the temperature, the solvent, the concentration and the counterion. It has been shown that the line width of the resonances increases with increasing size of the alkyl group, i.e. with increasing molecular mass of the species under investigation; in fact, the isotropic motion of a solute in a mobile liquid can be

correlated to the correlation time τ_c by

$$\tau_c = \frac{4\pi\nu a^3}{3k_B T} \quad [4]$$

where ν is the viscosity of the solution and a is the radius of the ‘spherical’ molecule. Moreover in the case of these small molecules, the hypothesis of extreme narrowing conditions ($\tau_c^2\omega^2 \ll 1$, i.e. fast molecular motions with respect to the resonance frequency) seems very likely to be valid.

Combining eqns [3] and [4], a linear plot of $\Delta\nu_{1/2}$ vs the experimentally measurable value ν/T is observed. The $\Delta\nu_{1/2}$ values, unlike ^{75}As chemical shifts, are generally strongly dependent on the type of solvent employed, partly surely owing to ion pairing; in fact, the line widths for $(\text{AsEt}_4)^+\text{Br}^-$ are reported to be 168, 455, 670 and 700 Hz in water, acetonitrile, dimethylformamide and dimethyl sulfoxide, respectively. Finally, the concentration of the sample influences the arsenic line width, whereas the counterion seems not to play a significant role in temperature variation.

Applications

NMR spectroscopy of ^{75}As , $^{121,123}\text{Sb}$ and ^{209}Bi is arousing increasing interest. ^{75}As , $^{121,123}\text{Sb}$ and ^{209}Bi NMR studies have been found to be very useful for structural characterization in solutions of very weakly coordinating anions such as $[\text{M}(\text{OTeF}_5)_6]^-(\text{M} = \text{As, Sb, Bi})$. These are able to stabilize Meerwein salts (tertiary carbonium salts) and cations such as Cs^+ , Rb^+ , K^+ and Na^+ can help in the development of the field of stable carbocation chemistry and of protosolvated superelectrophiles.

^{75}As NMR spectroscopy has been applied in solution in elucidating the structures of heteropoly oxometalates $(\text{AsM}_{12}\text{O}_{40})^{3-}$ ($\text{M} = \text{W}$ or Mo), currently known as ‘Keggin’ anions, which are important in both fundamental and applied studies.

In some cases, ^{75}As relaxation of the $(\text{AsF}_6)^-$ ion has been employed for probing anion sites in proteins by analysing the band shape of the ^{19}F multiplets in terms of the transition probabilities for ^{75}As relaxation. Outside the motional narrowing limit, the transition probabilities $P_{m,m+1}$ and $P_{m,m+2}$ for ^{75}As relaxation become unequal. However, the actual transition probabilities dominating the line shape are weighted averages of those in the free and bound states, since binding usually occurs under fast exchange limit conditions. In this way, it has been possible to reproduce the experimental ^{19}F line shape for the binding of $(\text{AsF}_6)^-$ to human serum albumin.

Finally, a ^{75}As solid-state NMR study has been done on the measurement of isotropic indirect coupling to gain a better understanding of the electronic nature of semiconductor solids of the binary 13–15 type compounds,

such as GaAs. ^{75}As NMR has also been used to study the microscopic magnetic behaviour of an incipient heavy-electron compound UAs. It has been reported on the basis of the temperature dependence of the energy scale of the spin fluctuation that the relative importance of the exchange interaction with respect to the single-site dynamics in the moment relaxation generally increases on going from UP to UAs.

Symbols

I	spin
J	coupling constant
P_u	elements of the bond-order charge-density matrix (expresses population of the np orbitals and a p -electron 'imbalance' about the nucleus in question)
r	radius of the valence p orbitals (r^{-3} is usually called the orbital expansion term)
δ	chemical shift
ΔE	average electronic excitation energy
σ	nuclear screening constant
σ_{para} and σ_{dia}	local paramagnetic and diamagnetic, respectively, contributions to the nuclear screening constant

Introduction

The naturally occurring nuclei of the Group 13 elements, ^{10}B and ^{11}B , ^{27}Al , ^{69}Ga and ^{71}Ga , ^{113}In and ^{115}In , ^{203}Tl and ^{205}Tl , are magnetic and thus NMR-accessible. The receptivities of these nuclei are quite high and, except for thallium, the resonance frequencies are convenient for most multinuclear spectrometers. The relevant NMR properties of these nuclei are summarized in **Table 1**. With the exception of thallium all the nuclei possess a quadrupolar moment. Thallium nuclei with spin-1/2 have a relaxation time much longer than that characteristic of the lighter nuclei. Due to the quadrupolar nature of those nuclei, resonance signals are broadened in all environments, except those where the electric field gradient approaches zero, while the quadrupolar line width effect increases down the group. In the case of ^{115}In , the quadrupole moment is significantly large and only highly symmetric compounds are observable using ^{115}In NMR, even these producing extremely broad lines.

From the two naturally occurring boron isotopes, ^{11}B is more advantageous for NMR investigation and only this nucleus is usually studied. This is due to its higher degree of abundance and its lower nuclear spin. For gallium the ^{69}Ga nucleus, due to its significantly lower receptivity and despite its greater abundance, is considerably less favourable than the ^{71}Ga nucleus. ^{115}In and ^{205}Tl have superior receptivities and higher natural abundances than the other natural isotopes of these elements, and are preferred for indium and thallium NMR. Later in this article, NMR spectroscopy of the preferred nuclei will be discussed.

Nuclei of the Group 13 atoms have been used as NMR probes, especially in view of being able to identify molecular structures, to monitor reaction courses, detect intermediate species, and indicate chemical equilibria in exchange reactions. In general, the relative importance of the heteronuclear NMR technique is dictated by the chemistry of certain elements and because of this ^{11}B NMR and ^{27}Al NMR have been used most extensively. Structural evidence of molecules is mainly deduced from the chemical shift values. Correlations between chemical shifts and chemical parameters, such as coordination environment, different types of π -interaction, electronegativity, charges, etc., may be observed. Very often no one factor controls the chemical shift, but a combination of several interactions may be balanced to control the chemical shifts. Therefore, conclusions with respect to the structure of compounds in solution can be drawn usually from the chemical shifts when a sufficient amount of experimental data is available for comparison. In some cases, efficient techniques for calculating NMR chemical shifts may provide valuable data, strongly supporting the interpretation of experimental chemical shifts (particularly the individual gauge for the localized orbital method, IGLO, and the gauge-including atomic orbital method, GIAO).

Since a chemical shift is the most informative characteristic of heteronuclear NMR, it is, therefore, of interest to indicate briefly the factors affecting the chemical shift of a nucleus. Generally, the chemical shifts are affected by local diamagnetic (σ_{dia}) and paramagnetic (σ_{para}) contributions to the nuclear screening constant (σ): $\sigma \cong \sigma_{\text{para}} + \sigma_{\text{dia}}$. The diamagnetic contribution in the

Group 13 nuclei is generally assumed to be relatively small compared with the observed chemical shift range, and remains roughly constant for each nucleus despite dramatic changes of the nucleus chemical environment, since in chemical bonding the core electrons are relatively unperturbed. Hence, the paramagnetic shielding term is considered to be responsible for the variation observed in the chemical shifts and it results from the local anisotropic motion of the valence electrons surrounding the nucleus in question. The local paramagnetic term σ_{para} depends to a first approximation on the average electronic excitation energy ΔE , the average radius of the valence orbitals and the symmetry of the distribution of bonding electrons around the nucleus in question. A convenient form of description of the local paramagnetic shielding term is the expression based on Ramsey's nonrelativistic approach:

$$\sigma_{\text{para}} \sim \Delta E^{-1} \langle r^{-3} \rangle_{2p} P_u \quad [1]$$

The value of σ_{para} is larger the lower the energy of the excited states involving a rotation of charge (ΔE is small), the more asymmetric the distribution of p electrons (the P_u term is large) and the closer they are to the origin (the radial term is large). An electronegative neighbouring atom increases the effective nuclear charge on the atom in question, thereby increasing the $\langle r^{-3} \rangle_p$ term and increasing σ_{para} . But even for closely analogous compounds, the electronegativity argument must be used with care since other effects may alter the radius and energy terms in σ_{para} in a complex fashion. Therefore, for Group 13 compounds the substituent effect, for instance, may affect the shielding, often in a way not yet completely understood. According to the above consideration concerning the factors determining the chemical shift, a greater range of chemical shifts may be expected for the three-coordinate than for the four- and higher coordinate Group 13 compounds. In the former there is a p orbital available for π -interaction with the heteroatom lone pair. Due to this interaction a significant variation in orbital angular momentum will be present resulting from the wide variation of strength and number of π -donor ligands. This type of interaction is not available for the four-coordinate complexes since all the valence orbitals are involved in the σ bond formation.

Much less attention has been paid to magnetic relaxation measurement of the Group 13 element nuclei which may provide useful information in the study of molecular motion and interactions, and the symmetry of the nuclear environment. Nuclear magnetic relaxation is usually described both in terms of the methods of coupling of the local magnetic field with the spin system (the spin-lattice and spin-spin relaxation) and the different mechanisms. There are a number of different nuclear magnetic relaxation mechanisms: the quadrupolar mechanism which

governs the relaxation behaviour of most quadrupolar nuclei, the spin-spin rotation and the chemical shift anisotropy mechanisms (important for spin-1/2 heavy metal ions), the magnetic dipole-dipole interaction of two nuclei (which is the predominant relaxation mechanism for instance for ^{13}C nuclei with directly bonded hydrogen), the scalar coupling mechanism, and relaxation induced by the presence of unpaired electrons. The contribution of the individual relaxation mechanisms to the overall relaxation rate is additive. Nuclei with spin $I \geq 1$ have unfavourable characteristics arising from the quadrupole moment which interacts with the electric field gradient created by the surrounding electrons. This leads to a decrease of relaxation times and, accordingly, an increase of the line widths.

^{11}B NMR Spectroscopy

Boron was among the first elements to attract the attention of NMR spectroscopists in the 1950s. The ^{11}B nucleus has a relatively small quadrupole moment and the NMR line widths are relatively sharp, ranging between 2 and 100 Hz, usually in the 30–60 Hz range. Occasionally, such as for $(\text{R}_2\text{N})_2\text{B}^+$ borinium cations, the line widths increase greatly to 400–800 Hz owing to the more rapid relaxation associated with an increase in the nuclear field gradient. Boron NMR spectroscopy has found widespread application in boron chemistry. The ^{11}B chemical shifts, intensity of ^{11}B resonances and coupling constants between boron and other nuclei are very useful for the elucidation of molecular structures and for control of reactions involving boron compounds. The peak area of a resonance is proportional to the number of boron atoms in the respective chemical environment. The chemical shift is affected by the chemical environment of the boron nucleus under investigation, i.e. the coordination number and the nature of substituents directly attached to the boron atom, and the chemical shift can be readily correlated with structure. The ^{11}B chemical shifts of boron compounds cover a range of about 250 ppm. The solvent effect on $\delta^{11}\text{B}$ is of small magnitude and can usually be neglected. Noticeable solvent shifts (up to 4 ppm) have been observed only for some polyhedral boranes and related compounds. $\text{BF}_3 \cdot \text{OEt}_2$ is a reference compound, usually employed as an external standard. Several correlations of $\delta^{11}\text{B}$ with structural parameters in molecules have been established. The number of reported ^{11}B NMR data is enormous. Almost any new boron-containing compound has been subjected to structural analysis by ^{11}B NMR. In general, ^{11}B NMR measurements are applied in two areas: organoboranes and miscellaneous compounds, and boron polyhedral borane derivatives. The first area encompasses research in organic synthesis chemistry and on the structure and dynamics of boron compounds in solution.

^{11}B NMR provides important information on the electronic environment of a boron atom and can be useful in predicting some of the chemical behaviour of boron compounds. The second area is largely a domain of elucidation of the structure and bonding in polyhedral boranes, carboranes, azaboranes, metallaboranes and related compounds.

Organylboranes and Miscellaneous Compounds

Two-coordinate boron compounds are relatively rare. The ^{11}B chemical shifts of $(\text{R}_2\text{N})_2\text{B}^+$ borinium cations

cover a narrow range of 35–38 ppm. However, the $\delta^{11}\text{B}$ values of iminoboranes, $\text{R}-\text{B}\equiv\text{N}-\text{R}'$, fall in the range of 3 to 22 ppm and are sensitive to the nature of the substituents at the site of the imino nitrogen atom. The trend in the ^{11}B shifts corresponds closely to that observed for the ^{13}C chemical shifts of similarly substituted alkynes.

^{11}B chemical shifts have proved to be an extremely valuable tool for distinguishing between three- and four-coordinate boron compounds. Chemical-shift data of representative compounds are given in Table 2. Furthermore, a schematic structure representation of compounds [1]–[5] with the corresponding chemical shift values provides a good illustration of the

power of ^{11}B NMR for intimate understanding of the nature of π -interactions in boron compounds. In trialkylboranes of a trigonal planar structure [1] the p orbital remains unoccupied (π -bonding is not an obvious possibility), resulting in a great imbalance of bonding electrons around the boron atom and leading to a large shift of the ^{11}B NMR signal to low field ($\delta \sim 86$ ppm). By contrast, another triorganylboration compound, 7-borabicyclo[2.2.1]heptadiene ([2], $\delta = 5$ ppm), exhibits a significant upfield shift, and the magnitude of this shift is rationalized in terms of the interaction of the empty p orbital on boron with the π -clouds of two $\text{C}=\text{C}$ bonds. ^{11}B NMR spectroscopy has also been commonly employed to provide information about the contribution of π -bonding between boron and carbon centres in many other cyclic and open-chain unsaturated organylboron compounds, i.e. vinylboranes, alkynylboranes, allylboranes, borinenes, boroles and boron derivatives of six-membered rings.

Referring to the R_3B compounds, replacement of the R substituent by a strong electronegative atom or ligand X with a lone pair available for π -interaction results in a high-field shift. For example, the δ ^{11}B values for three-coordinate $\text{R}_2\text{BNR}'\text{R}''$ and $\text{R}_2\text{BOR}'$ compounds are found approximately in the range 44–50 ppm and 50–55 ppm, respectively. Hence, the ^{11}B signal of Et_2B (benzoinato) [4] at 55 ppm is indicative of a three-coordinate environment at boron with the uncoordinated carbonyl group of the bifunctional benzoinato ligand. In this case ^{11}B NMR gives an accurate picture of the π -interaction and is additionally a good indicator of the relative strength of a boron–oxygen π -bond vs. a boron–carbonyl dative bond. It is worth noting that the solution structure of compound [4] is consistent with that found in the solid state. From the differences in ^{11}B chemical shifts of three-coordinate diorganylboration R_2BX the following order of increasing π -interaction for various X results: $\text{PR}_2 < \text{SR} < \text{Cl} < \text{OR} < \text{NR}_2 < \text{F}$. This is only a qualitative interpretation and a quantitative correlation should not be expected from chemical shift values since the magnitude of the shift may be influenced by other electronic and steric effects, e.g. various functionalities of the ligand X have a remarkable influence on the ^{11}B nuclear shielding. Further successive replacement of an alkyl group by the ligand X leads to a progressive upfield shift of ^{11}B resonances and the magnitude of shift depends on the nature of the substituent X. Minor changes in the chemical shift values are observed for sulfide and then for chloride derivatives, and more significant changes are for $\text{X}=\text{OR}$, NR_2 and F. A great variety of non-cyclic RBX_2 and cyclic $\text{RB}(\text{X},\text{X})$ compounds have been studied by ^{11}B NMR spectroscopy. It is interesting to note that for BX_3 compounds the order of increasing substituent effect is somewhat different from that for R_2BX diorganylboration: $\text{SR} < \text{Cl} < \text{NR}_2 < \text{OR} < \text{F}$. ^{11}B

NMR is extremely useful in the investigation of the chemistry of three-coordinate diborane compounds, $\text{X}'\text{X}''\text{B}-\text{BX}'\text{X}''$. The presence of the B–B bond is reflected in the ^{11}B resonance low-field shift compared with that in the corresponding organylboranes $\text{RBX}'\text{X}''$.

^{11}B NMR is very useful in the investigation of the rich chemistry of transition metal complexes with boron-containing heterocycles like borole and borabenzene derivatives or various boron–nitrogens and boron–oxygen cyclic compounds. In general, the metal–boron bonding interaction is reflected by a ^{11}B high-field shift compared with that of the corresponding heterocycles. In the triple-decker complexes, the boron of the bridging ligand (to which two metals are bonded) is more shielded than that in the end or capping boron-containing ring to which only one metal atom is bonded.

^{11}B NMR provides valuable information concerning the interaction between three-coordinate boranes and donor ligands and enables prediction of some of the chemical behaviour. The formation of the four-coordinate Lewis acid–base adducts is evident from the ^{11}B NMR spectrum. When the coordination number of boron increases from three to four, an upfield shift of the ^{11}B resonance is generally observed. The interaction between a borane and a donor ligand often results in a dynamic equilibrium and ^{11}B NMR measurements at variable temperatures are particularly helpful for investigations of this type of equilibrium. The influence of various ratios of donor and acceptor molecules upon the equilibrium can be determined by ^{11}B NMR spectroscopy. However, the utility of ^{11}B NMR to determine the Lewis acid strength of three-coordinate boranes is strongly limited, since the magnitude of chemical shift change upon coordination reflects the π -bonding effect in a parent borane as well as the sensitivity to steric factors. Similarly, an observed order of ligand basicity usually corresponds to certain boron-system affinities and is strongly affected by steric effects. The structures of dialkylboron derivatives of saturated and unsaturated hydroxy carbonyl compounds, Et_2B (benzoinato) [4] and Et_2B (maltolato) [5], are a good illustration of the importance of π -bonding between boron and oxygen. The ^{11}B signal of [5] at 22 ppm is significantly shifted to high field when compared with that for complex [4] and the chemical shift value falls in the region associated with neutral, four-coordinate boron nuclei. This result is consistent with the chelation of the carbonyl group to the boron atom and the four-coordinate chelate structure [5] in solution. Thus, these data, based on ^{11}B NMR and X-ray crystallographic studies, provide strong evidence that for organylborane derivatives of unsaturated hydroxy carbonyl compounds the π -interaction of the alkoxide oxygen lone pairs with the chelate-ligand-extended π system may dominate and effectively obstruct the boron–oxygen π -interaction.

Many coupling constants between directly bonded nuclei can be obtained from ^{11}B NMR spectra, especially for four-coordinate boron, where in many cases the quadrupolar relaxation rate is sufficiently slow. The accuracy is somewhat limited because of the line width of the resonance signals. Therefore, the use of a high magnetic field strength is advantageous. One-bond $^{11}\text{B-X}$ coupling constants from 1 to 5 Hz in BF_4^- up to more than 1000 Hz for $\text{X} = ^{119}\text{Sn}$ or ^{207}Pb have been observed. For terminal boron-hydrogen bonds, the $^1J(^{11}\text{B-}^1\text{H})$ values are in the range 100–190 Hz, but when a hydrogen bridge is involved $^1J(^{11}\text{B-}^1\text{H})$ is less than 80 Hz. Thus, it is possible to use these coupling constants to determine the coordination at each boron in a boron hydride when resolution permits. Despite the wide use of ^{11}B NMR for the characterization of boron compounds, relatively little attention has been paid to ^{11}B relaxation. Typical values for relaxation times of ^{11}B nuclei are in the range of 10–200 ms, commonly 10–50 ms.

Polyhedral Boranes

The development of boron cluster chemistry is intimately coupled with ^{11}B NMR which has been the most efficient method of elucidating the structure and bonding in polyhedral boranes and related clusters. At present, based on a great amount of ^{11}B NMR experimental data, meaningful conclusions with respect to the structure of boron skeleton compounds in solution can be drawn from the chemical shifts. Polyhedral boranes are electron-deficient systems involving multicentre bonding, i.e. B–H–B, B–B–B, B–C–B, and with highly delocalized skeletal electrons. The majority of boron vertices in

borane clusters are formally sp^3 hybridized; deviation from the ideal tetrahedral geometry, i.e. the imbalance of bonding electrons, is the most important factor affecting the chemical shift of individual skeletal atoms. In borane cluster compounds the influence of electron density of individual skeletal atoms on chemical shift is significant, but is not the primary factor. ^{11}B chemical shift values of polyhedral boranes and related clusters span approximately 75 to -60 ppm. Many empirical rules for predicting $\delta^{11}\text{B}$ values have been established which are based on various effects including those related to the coordination number, bridging hydrogens, *endo*- and *exo*-cluster substituents, cluster shape and antipodal atoms. For example, the replacement of a boron nucleus in a polyhedral borane by a heteroatom results in a downfield ^{11}B chemical shift for the boron across the cage from the heteroatom, usually the so-called antipodal effect. The largest effect was observed for the antipodal boron B(10) in the 10-vertex series *closo*-1- EB_9H_9 heteroboranes, e.g. $\delta^{11}\text{B}$ values of B(10) are -2.0 , 28.4 and 74.5 ppm for $\text{E} = \text{BH}^{2-}$, CH^- and S , respectively. Two-dimensional (2D) NMR techniques, i.e. $^{11}\text{B-}^{11}\text{B}$ 2D COSY and $^1\text{H-}^{11}\text{B}$ 2D spectra, usually allow unambiguous ^1H and ^{11}B signal assignments for most polyhedral boranes. In applying the *ab initio*-IGLO-NMR technique, the various competitive structures are subject to *ab initio* structural optimization, following which IGLO calculations are used to predict the sets of ^{11}B chemical shift values to be expected of each *ab initio* optimized structure.

^{27}Al NMR Spectroscopy

The first ^{27}Al NMR measurements were performed in the early 1960s, but the 1980s and 1990s brought a considerable increase in investigations of the nature of aluminium compounds using ^{27}Al NMR spectroscopy. The usual reference for chemical shifts is $[\text{Al}(\text{H}_2\text{O})_6]^{3+}$ (an acidic solution of Al(III) salt, line width several Hz) or $\text{Al}(\text{acac})_3$ in benzene solution (line width ~ 100 Hz; acac = acetylacetonate). The ^{27}Al NMR chemical shifts of the most often studied organometallic and inorganic aluminium(III) compounds cover a range of approximately 350 ppm, from 290 to -60 ppm. However, there are some rare examples such as the $[\text{Cp}_2\text{Al}]^+$ cation ($\delta -126.4$ ppm) ($\text{Cp} = \text{C}_5\text{H}_5$) or the salts with transition metals, i.e. $\text{Co}(\text{AlCl}_4)_2$ ($\delta -225$ ppm). The line width of ^{27}Al resonances is highly sensitive to the symmetry of the aluminium coordination sphere and ranges from a few Hz for highly symmetric species to a few kHz. However, in some cases the resonance may even be undetectably broad and a given spectrum does not display all the response of the aluminium nuclei present. In the standard ^{27}Al NMR spectrum the intensity ratio of resonances

cannot usually be interpreted quantitatively with respect to the number of aluminium atoms in the respective chemical environment, due to this strong effect on line widths.

Currently, almost any new organoaluminium compound is routinely characterized by ^{27}Al NMR. Earlier investigations suggested that the observed ^{27}Al chemical shift is diagnostic of the compound coordination state. However, an increasing amount of experimental data has shown that the chemical shift ranges corresponding to the different coordination states largely overlap and a certain value may not be simply interpreted according to the number of ligands. Shielding data subdivided with respect to the aluminium coordination number, presented graphically in **Figure 1** and for a series of compounds collated in **Table 3**, show that the nature of substituent functions significantly governs the ^{27}Al NMR chemical shifts. Hence, although characterization of organoaluminium compounds by ^{27}Al NMR has become routine, the ^{27}Al NMR spectra still pose significant interpretational difficulties. Additionally, the important difficulty in

resonance identification is also due to a background signal that in some cases (especially for dilute solutions) may dominate in a measured spectrum (**Figure 2**). This relatively broad 'probe head signal' falls at about 60 ppm and when this region of the spectrum is of interest then it is advisable to use relatively highly concentrated solutions and to identify possible extraneous signals with blank samples.

Because of the relatively fast relaxation of the ^{27}Al nucleus, spin-spin coupling is not generally observed in ^{27}Al NMR spectra. However, a number of coupling constants have been reported. The $^1J_{\text{AlH}}$ and $^2J_{\text{AlH}}$ coupling constants were found to be 174 Hz and 6.3 Hz, respectively. The observed $^1J_{\text{AlP}}$ and $^2J_{\text{AlP}}$ coupling constants are in the range of 90–290 Hz and 6–30 Hz, respectively. The $^1J_{\text{AlF}}$ is ~ 19 Hz, $^1J_{\text{AlB}}$ is ~ 9 Hz, $^1J_{\text{AlC}}$ is ~ 73 Hz and $^1J_{\text{AlN}}$ is ~ 22 Hz. Only a few investigations have been made of the spin-lattice and spin-spin relaxation times of the ^{27}Al nucleus. Relaxation of the ^{27}Al nucleus is dominated by the quadrupolar interaction, as expected from its relatively high quadrupolar moment. For highly symmetrical species the relaxation rates are a few Hz and other relaxation mechanisms may be significant. For example, the relaxation of the ^{27}Al nucleus in the solvate complex $[\text{Al}(\text{CH}_3\text{CN})_6]^{3+}$ and in anions $[\text{AlCl}_n\text{Br}_{4-n}]^-$ proceeds by means of the quadrupole and scalar mechanisms.

Figure 1 ^{27}Al chemical shift ranges of aluminium compounds, demonstrating the dependence of aluminium shielding on the nature of the coordination environment and the coordination number (CN) of the aluminium atom. L is a monodentate ligand (e.g. NR_3 , pyridine, OR_2 , $\text{R}_2\text{C}=\text{O}$, H_2O , PR_3 , SR_2) or may denote a neutral chelating group from a monoanionic bidentate ligand (e.g. the carbonyl group in chelate complexes [6] and [9], hence the coordination environment of these complexes is described as $\text{C}_2\text{AlO}(\text{L})$ and $\text{C}_2\text{AlO}(\text{L})_2$, respectively) as well as one of the bridging alkoxide oxygen atoms in associate compounds (e.g. an alkoxide oxygen atom in dimer [8]). X is a ligand carrying one negative charge (e.g. H, R, OR, OH, halogen).

Organoaluminium(III) and Miscellaneous Compounds

Various factors that influence the aluminium nuclear shielding may be employed for specifying different organoaluminium species in solution. Thus, the chemical shifts for the three-coordinate aluminium compounds range from 260 to 0 ppm, and the electronic nature of the ligand determines the extent of metal shielding. The majority of large chemical shift resonances of large chemical shift are generally exhibited by the coordinatively unsaturated three-coordinate R_3Al compounds (~ 260 ppm). Successive replacement of the alkyl substituent by a sterically hindered aryloxy ligand leads to a progressive decrease in chemical shift of the ^{27}Al resonance in the series of three-coordinate monoaryloxy (~ 190 ppm), bisaryloxy (~ 100 ppm) and trisaryloxy (~ 0 ppm) compounds. These phenomena can be explained in terms of a π -interaction between the aluminium empty p orbital and the aryloxy oxygen lone pairs. The increasing number of strong electronegative aryloxy ligands attached to aluminium probably enhances the π -acceptor strength of aluminium and strengthens the Al–O π -bonding, which leads to decreasing chemical shift. In the corresponding four-coordinate Lewis acid–base adducts, $\text{R}_3\text{Al}(\text{L})$, the aluminium nucleus is significantly shielded due to the new

dative bond formed and ^{27}Al chemical shifts are substantially smaller than that of the parent monomeric three-coordinate compound. A similar behaviour results when the alkyl groups in $\text{R}_3\text{Al}(\text{L})$ are successively replaced by aryloxy substituents, although in this case the

observed decrease in chemical shift is not as great as for three-coordinate compounds. For the four-coordinate AlX_4^- anionic species, where $\text{X} = \text{H}, \text{R}, \text{halogen}, \text{OH}$ or OR , an appreciable increase in chemical shift is observed for the tetraalkylaluminium anions and a decrease is found for the AlI_4^- anion. The $\delta^{27}\text{Al}$ values of AlX_4^- generally follow the electronegativity of X , and some discrepancies may be attributed to the anisotropic contribution of various ligands because no π -bonding is likely to take place in these anions. These highly symmetrical species can be easily identified by their chemical shift and by the very sharp resonance.

Extensive X-ray work has revealed a large variety of solid-state structures of cyclopentadienylaluminium compounds. In combination with the X-ray data, ^{27}Al NMR spectroscopy in solution provides information about the contribution of π -bonding between aluminium and carbon centres. For example, inspection of selected data for the three- and four-coordinate cyclopentadienyl-aluminium complexes collated in **Table 3** shows that the shielding effect is most pronounced for situations where the aluminium centre, irrespective of its coordination number, bears electronegative substituents. This is consistent with the expectation that the electron-withdrawing group should enhance π -bonding in that Al-Cp interaction.

The $\delta^{27}\text{Al}$ values for an extensive series of the four-coordinate $\text{R}_2\text{Al}(\mu\text{-X})_2\text{AlR}_2$ compounds with alkoxide or amide bridging ligands fall in a very narrow range of approximately 160–140 ppm. In the same range are observed chemical shifts of a substantially different class of compounds, the monomeric four-coordinate dialkylaluminium chelate complexes $\text{R}_2\text{Al}(\text{X}, \text{Y})$, where $\text{X}, \text{Y} = \text{O}, \text{O}'-, \text{O}, \text{N}'- \text{ or } \text{N}, \text{N}'-$ unsaturated bifunctional ligands with both unsaturated bifunctional atoms involved in a π conjugated bond system. However, a pronounced change in the shielding of aluminium resulting from the replacement of both R substituents in the $\text{R}_2\text{Al}(\text{O}, \text{O}')$ -type complexes by chloride or alkoxide ligands is reflected by increased shielding of the ^{27}Al resonance of approximately 60 ppm or 110 ppm, respectively. A unique shielding situation arises for the dialkylaluminium chelate derivatives of saturated ketone-functionalized alcohols. This group of compounds exists in solution as an equilibrium mixture of the four-coordinate monomer $\text{R}_2\text{Al}(\text{O}, \text{O}')$ and the five-coordinate dimer $[\text{R}_2\text{Al}(\text{O}, \text{O}')]_2$. The monomeric chelate complexes have ^{27}Al shielding greater than those of related dialkylaluminium complexes derived from the unsaturated hydroxy carbonyl compound. This is illustrated by complexes $\text{Me}_2\text{Al}(\text{hacac})$ [6] and $\text{Et}_2\text{Al}(\text{acet})$ [7] (where $\text{hacac} = \text{deprotonated 2-hydroxyacetophenone}$, $\text{acet} = \text{deprotonated 3-hydroxy-2-butanone}$) and the corresponding chemical shift values. Furthermore, there is observed a decreased shielding of the ^{27}Al resonance with the association of monomeric species to the

five-coordinate adduct which is opposite to the expected coordination number effects, e.g. [7] (δ 122 ppm) and $[\text{Et}_2\text{Al}(\text{acet})]_2$ [8] (δ 131 ppm). The observed relatively high shielding of aluminium in the four-coordinate dialkylaluminium derivatives of saturated ketone-functionalized alcohols was reasonably explained by π -donation from the alkoxide-oxygen lone-pair orbitals to the σ^* antibonding orbital of the dative bond between the aluminium atom and the oxygen atom of the chelating carbonyl group. This type of interaction is rather unlikely for the related aluminium compounds with unsaturated chelating ligands due to the involvement of oxygen lone pairs in a chelate conjugated bond system. Thus ^{27}Al NMR spectroscopy may be diagnostic of another type of π -interaction, i.e. π -bonding between the alkoxide oxygen lone pairs and $\text{Al-X } \sigma^*$ antibonding orbitals in four-coordinate aluminium alkoxides.

Simple monomeric five-coordinate aluminium complexes are usually relatively unstable and/or highly reactive (when not stabilized by multidentate ligands) and ^{27}Al NMR spectroscopy becomes a powerful tool for the characterization of these species in solution. The available $\delta^{27}\text{Al}$ data show that the aluminium chemical shifts in the series of the five-coordinate organoaluminium compounds varies with the number of alkyl groups attached to aluminium. The $\delta^{27}\text{Al}$ values of the five-coordinate dialkylaluminium complexes span a relatively narrow range of approximately 135–100 ppm, irrespective of whether they occur as monomeric or dimeric moieties, e.g. $\text{R}_2\text{Al}(\text{O}, \text{O}') \cdot \text{L}$ or $[\text{R}_2\text{Al}(\text{O}, \text{O}')]_2$. The nature of chelate ligands bonded to aluminium does not affect significantly the ^{27}Al chemical shift. Furthermore, for the dialkylaluminium chelate derivatives of unsaturated hydroxy carbonyl compounds, $\text{R}_2\text{Al}(\text{O}, \text{O}')$, the observed shielding effect on the five-coordinate adduct formation, $\text{R}_2\text{Al}(\text{O}, \text{O}') \cdot \text{L}$, is approximately in the range of 40–15 ppm, e.g. the shielding effect for the chelate complex [6] and its adduct with γ -picoline [9] is 16 ppm. For the monoalkylaluminium five-coordinate compounds, an increase in shielding with respect to the dialkylaluminium derivatives is observed and their $\delta^{27}\text{Al}$ fall in the range of 70–50 ppm (see for example $\text{MeAl}(\text{hacac})_2$ [10]).

Al^{3+} Species in Solution

For years, ^{27}Al NMR spectroscopy has been extensively used to investigate the physical and chemical properties of aluminium salts in polar solvents with regard to solvation, ion pairing, hydrolysis and complexation. These studies involve mainly the octahedrally coordinated aluminium species since the solvates of Al^{3+} are octahedral, except where steric restrictions favour lower coordinated complexes. A correlation between the chemical shifts of aluminium hexasolvated complexes

and the donor number (DN) (empirical scale of Lewis basicity) of the ligand has been observed, as might be expected for a metal ion with a large charge density whose chemical shift is dominated by the σ_{para} term. Al(III) solvation and ion pair $[\text{Al}(\text{H}_2\text{O})_n\text{L}_{6-n}]^{3+}$ complexes can be readily studied. Quadrupole broadening usually precludes the observation of signals for geometrical isomers of these complexes. The $\delta^{27}\text{Al}$ for certain Al^{3+} species is essentially independent of solution concentration and solvent composition. This indicates that the metal-ion electronic environment and subsequent chemical shift depend only on the composition of the principal solvation shell, and are not influenced by long-range outer-shell effects. For the octahedrally coordinated aluminium species $[\text{Al}(\text{L}^1)_{6-n}(\text{L}^2)_n]^{3+}$, when a L^1 ligand is gradually replaced by a L^2 ligand, the induced shift is usually additive. Very often the ligand exchange rate is slow enough to permit the observation of several solvated species and the kinetic and thermodynamic parameters may be determined.

^{27}Al NMR investigations play an important role in the control of the degree of hydrolysis and further of the polymerization of the aqueous Al(III) solution. Various aggregates give distinctive resonances of different AlO_4 , AlO_5 and AlO_6 moieties, e.g. species such as the dimer $[\text{Al}_2(\text{OH})_2(\text{H}_2\text{O})_8]^{4+}$ and the polyoxocation $[\text{AlO}_4\text{Al}_{12}(\text{OH})_{24}(\text{H}_2\text{O})_{12}]^{7+}$ were identified. ^{27}Al NMR

spectroscopy can be used to study the characterization of Al^{3+} species in aqueous solution over a wide range of concentration and pH. For example, a conceptual basic drawback in the interpretation of aluminium toxicological data lies to a great extent in the ill-defined nature of the aluminium species administered at physiological pH and in the absence of strongly complexing agents. Hence, there are numerous applications of ^{27}Al NMR measurements to probe biological processes, e.g. ^{27}Al NMR is a useful probe for the Al(III)–phosphate system and in this respect studies of aqueous solutions of Al(III) salts with biologically relevant phosphates were carried out.

Aluminium(I) Compounds

Monovalent aluminium compounds were first synthesized and characterized in the 1990s. The calculated $\delta^{27}\text{Al}$ for the Al(I) compounds cover a relatively large range, over 1000 ppm, and indicate that the shift depends strongly on the nature of the bonded ligand. There are only a few experimental data. For example, the chemical shift for AlCl in toluene–ether solution is 35 ppm and for the tetramer $[\text{Cp}^*\text{Al}]_4$ and the monomer Cp^*Al ($\text{Cp}^* = \text{C}_5\text{Me}_5$) in benzene the corresponding values are –80 ppm and –150 ppm, respectively. The observed line widths for the Al(I) compounds range from 100 to 1800 Hz.

Solid-State ^{27}Al MAS NMR

The increasing popularity of ^{27}Al NMR is strongly connected with high-resolution magic angle spinning (MAS) solid-state NMR, which allows investigation of polycrystalline and amorphous materials, which are of great practical importance. Understanding the structure of these materials is fundamental to many problems in materials science. High-resolution solid-state NMR is particularly valuable in quantifying the extent and nature of disorder. Another reason for the interest in solid-state studies is that the fluxional behaviour is often frozen out and consequently the NMR results are more amenable to correlation with X-ray studies, and these studies can act as a bridge between the crystal and solution structures. For example, ^{27}Al MAS NMR spectra have been extensively used to inspect the structural character of the aluminium species in zeolites. One of the most important applications yields the state of aluminium, shows the transformation of the zeolite symmetry, and yields access to the chemical status of the extra-framework aluminium species after stream treatment of zeolites. ^{27}Al MAS NMR is one of the main techniques for investigating cement, glasses, sol-gel precursors of the zeolites and other ceramic materials. Simple MAS spectra are usually limited by the low resolution generally caused by second-order broadening, and special techniques such as double rotation or two-dimensional MAS may be used to enhance the resolution.

^{71}Ga NMR Spectroscopy

^{71}Ga NMR spectroscopic studies are much less common due to the characteristically broad resonances, associated with the large quadrupole moment, and low receptivity, and partly because Ga chemistry has attracted much less attention than that of B or Al. The chemical shifts are referred to $[\text{Ga}(\text{H}_2\text{O})_6]^{3+}$. ^{71}Ga NMR data are rather sparse and at present no meaningful conclusion with respect to the structure of gallium compounds in solution can be drawn from an interpretation of the chemical shift values. However, in view of the significant structural similarity of analogous gallium and aluminium compounds it is reasonable to expect that the general observation concerning the correlation between ^{27}Al shifts and the structure of aluminium species may be transferred to gallium. Table 4 presents the ^{71}Ga chemical shifts for some gallium compounds.

^{71}Ga NMR spectroscopic studies have been used in the considerable research of the chemical nature of gallium(III) hydrolysis species. For example, it was found that the base hydrolysis of gallium(III) salt solutions led to the $[\text{GaO}_4\text{Ga}_{12}(\text{OH})_{24}(\text{H}_2\text{O})_{12}]^{7+}$ polyoxocation. However, much less of this species is formed than in the case of aluminium. Furthermore, ^{71}Ga NMR

spectroscopy can be used to study the structure and stability of gallium complexes. The clinical use of ^{67}Ga as a radioactive tracer in tumour scanning and the inhibition of cellular incorporation *in vivo* by citrate, phosphate and other chelating agents served as the impetus for these studies. For example, in order to provide complexes with potentially greater *in vivo* stability with respect to acid-catalysed dissociation, model complexation studies with amino phosphonic acids have been carried out. It was found that the tripodal amino phosphinato ligand, tris[4-(phenylphosphinato)-3-methyl-3-aza-butyl]amine (H_3ppma), forms stable complexes of octahedral geometry at extremely low pH, a regime in which potentiometry is of no use for studying the solution chemistry. Other methods were sought to determine the stability constants, with NMR spectroscopy proving to be the only suitable tool. The highly symmetric environment around the metal centre in $[\text{Ga}(\text{H}_3\text{ppma})_2]^{3+}$ produces a low electric field gradient at the gallium nucleus, leading to an unusually narrow line (50 Hz) in the ^{71}Ga NMR spectrum. The narrow resonances made the complex amenable to stability constant studies via a combination of ^{71}Ga and ^{31}P NMR spectroscopies as illustrated in Figure 3. The chemical shifts observed for the gallium complexes are indicative of octahedral geometries. The gradual disappearance of the resonance for $[\text{Ga}(\text{H}_2\text{O})_6]^{3+}$ (Ga) with the concomitant growth of the resonance for $[\text{Ga}(\text{H}_3\text{ppma})_2]^{3+}$ (GaL_2) is evident as R is increased (concentration ratio $R = [\text{H}_3\text{ppma}]/[\text{Ga}^{3+}]$). The $[\text{Ga}(\text{H}_3\text{ppma})(\text{H}_2\text{O})_3]^{3+}$ species (GaL) is barely observable as an insignificant broad resonance and is only seen when R is small. The relative intensities of the gallium resonances correlate with their respective ^{31}P NMR spectra. The latter consist of three major

Figure 3 ^{71}Ga (65.7 MHz) (left) and ^{31}P (121.0 MHz) (right) NMR spectra for the stability constant study of the Ga(III)– H_3ppma system ($R = [\text{H}_3\text{ppma}]/[\text{Ga}^{3+}]$). Reprinted with permission of the American Chemical Society from Lowe MP, Rettig SJ, and Orvig C (1996) *Journal of the American Chemical Society* 118: 10446–10456.

resonances corresponding to the two diastereoisomers of GaL_2 and to the free ligand L, respectively. The formation constant of the GaL_2 complex was determined from the integration of the ^{71}Ga and ^{31}P NMR spectra.

The +1 oxidation state of gallium represents a relatively unexplored area. There are only a few available data. For example, the ^{71}Ga chemical shift for benzene solutions of GaAlX_4 compounds shows a considerable dependence on the type of AlX_4^- anion and a decreased shielding of about 130 ppm was observed: from –680 ppm (AlCl_4^-) and –635 ppm (AlBr_4^-) to –552 ppm (AlI_4^-). The ^{71}Ga chemical shifts of GaAlX_4 were found to be solvent- and temperature-dependent. The observed line widths for the Ga(I) species are in the range of 80–1200 Hz.

^{115}In NMR Spectroscopy

The first NMR measurements of In(III) salts in aqueous solution were reported in the 1950s. However, ^{115}In has a relatively large quadrupole moment which reduces its observability. ^{115}In NMR studies of indium complexes in solids or melts of indium metals, alloys and salts have been carried out. Relatively few experimental results are available in solution. The adopted reference of chemical shift is $[\text{In}(\text{H}_2\text{O})_6]^{3+}$ and the reported line widths even for this symmetrical species are in the range of 1500–2000 Hz. For example, ^{115}In NMR studies of indium halide complex formation in an aqueous solvent mixture have been carried out. The chemical shifts were used along with the line widths to elucidate the chemical

equilibria and the exchange processes of indium halide complexes in HCl, HBr and HI aqueous solution and in water–acetone mixtures. The ^{115}In chemical shifts in the series of four-coordinate InX_4^- ions are 420 ppm (InCl_4^-), 180 ppm (InBr_4^-) and –440 ppm (InI_4^-) and follow a trend similar to that found for the analogous Al and Ga species. Furthermore, $\delta^{115}\text{In}$ for $[\text{In}(\text{H}_3\text{ppma})_2]^{3+}$ in CD_3OD solution is –14.6 ppm. The relaxation rates of the ^{115}In nucleus were obtained for $\text{In}(\text{ClO}_4)_3$ in aqueous HClO_4 , i.e. spin–lattice and spin–spin relaxation times of 0.33 ms and 0.24 ms, respectively.

^{205}Tl NMR Spectroscopy

^{205}Tl is among the most sensitive NMR nuclides and was investigated quite early on. The first liquid- and solid-state spectra for thallium were measured in 1953. The resonance frequency of ^{205}Tl demanded a single-frequency tuned probe, except for new probe designs at lower fields. Thallium provides significant contrast from the lighter Group 13 elements in terms of both nuclear properties (see Table 1) and chemical behaviour. For thallium the +1 oxidation state is normally the more stable, an exception among the Group 13 elements, where the +3 oxidation state dominates. ^{205}Tl is the fourth most receptive spin- $\frac{1}{2}$ nuclide. The sensitivity of the NMR parameters, such as chemical shift, the spin–spin coupling constant and the relaxation time, to the changes in the chemical environment of the thallium nucleus is more pronounced than is that of the lighter Group 13 nuclei; this is quite reasonable in view of the greater polarizability of the sixth-row elements. Therefore, ^{205}Tl NMR spectroscopy is quite useful for investigating such phenomena as ion-pairing, solvent–solute interactions, phase changes, long-range substituent effects and binding constants.

The chemical shift ranges are approximately 3400 ppm for Tl(I) and 5000 ppm for Tl(III) compounds. The lower oxidation state ^{205}Tl is appreciably shielded. The ^{205}Tl chemical shift is highly sensitive to the anion, solvent, concentration, phase change, substituents and temperature effects. For example, the chemical shift of the $^{205}\text{Tl}(\text{I})$ ion increased by about 2000 ppm as the solvent changed from water to liquid ammonia, and that of TlCl increased by 925 ppm from the melt to the solid. The anion- and concentration-dependent shifts are in the range of 10–100 ppm. The coupling constants involving the ^{205}Tl nucleus are usually large and vary significantly with changes in the physical and chemical environments. For example, $^1J_{\text{TIC}}$ is nearly 6000 Hz for CH_3TlX salts and $^2J_{\text{TlH}}$ ranges from –187 Hz to –1120 Hz for different organothallium(III) compounds. Only a few coupling constants have been observed for Tl(I) compounds due to the highly ionic nature of these complexes.

Tl(I) Species in Solution

^{205}Tl NMR has been used to determine ion-pair formation constants and the thermodynamic parameters of ion-pairing processes for Tl(I) salts in a number of solvents. The values of ion-pair formation constants have been found to be dependent on the dielectric constant of the solvent. A correlation between the ^{205}Tl chemical shift and the DN of the solvent has been indicated: the more basic the solvent, the lower the shielding of the Tl^+ ion. There have also been numerous studies of the preferential solvation of the Tl^+ ion in mixed solvent systems. The relative solvating abilities were analysed in terms of solvent donor-acceptor properties and the solvent DN was found to be most important in the preferential solvation.

An important application is the use of ^{205}Tl NMR measurements to probe biological processes in which Tl^+ replaces alkali cations; the Tl^+ ion has an ionic radius of 1.40 Å and in terms of size is close to K^+ . ^{205}Tl NMR has been useful in the study of a wide range of the Tl(I) complexes with synthetic and biological ionophores. The mode of complexation may be indicated by the solvent effect. For example, the chemical shifts of the cryptate complexes of the Tl^+ ion are usually independent of solvent, while those of the various Tl(I)-crown complexes are very solvent dependent. The latter reflect the open axial position of the Tl(I)-crown, where the solvent and anion interaction with the complexed ion occurs. A series of Tl(I)-antibiotics complexes has been characterized by the ^{205}Tl chemical shift and the spin-lattice relaxation. The trend in chemical shifts reflected the diversity of ligand used to bind the Tl^+ ion. On the other hand, the magnitude of the chemical shift anisotropy was diagnostic of the symmetry of the Tl^+ binding site, and the magnitude of the dipolar contribution to the spin-lattice relaxation indicated the proximity of hydrogen atoms. Hence, ^{205}Tl NMR shows great promise as a probe of the nature of metal binding sites.

Much effort has been expended in studying the relaxation behaviour of the $^{205}\text{Tl}^+$ ion in solution and has found application in the study of enzyme structure. The spin-lattice relaxation time of the Tl(I) was found to be very sensitive to environmental effects. For example, the $^{205}\text{Tl}^+$ spin-lattice longitudinal relaxation times T_1 were found to vary by over one order of magnitude for the solvent series, ranging from 1.8 s in water to 0.08 s in *n*-butylamine. The relaxation time of the Tl(I) ion aqueous solution was independent of concentration, and spin-rotation was found to be the dominant relaxation mechanism. In nonaqueous solution ion pairing becomes important and the longitudinal relaxation time of the Tl^+

ion is dominated by the chemical shift anisotropy mechanism. Furthermore, in the case of Tl^+ complexes with antibiotics, the longitudinal relaxation time is determined by the contribution from spin rotation, dipolar, and chemical anisotropy shift mechanisms. A strong influence of dissolved dioxygen on the $^{205}\text{Tl}^+$ relaxation rate has also been found. Therefore, it is advisable to use a degassed solution before attempting relaxation measurements.

Organothallium(III) and Miscellaneous Compounds

The ^{205}Tl chemical shifts of organothallium(III) compounds cover a range of over 2000 ppm and they display solvent dependence, although not as striking as that for Tl(I). Solvent basicity and ion pairing contribute to the solvent dependence. The dependence of the ^{205}Tl chemical shift of Me_2TlX salts upon solvent, concentration, X anion and temperature has been studied. The latter factor was found to affect the chemical shifts the most. Substituent changes produce large chemical shifts, for example the difference in chemical shift between Me_3Tl and Et_3Tl is 130 ppm. The relaxation behaviour of $^{205}\text{Tl(III)}$ has been investigated for Me_2Tl^+ in solution as a function of temperature and magnetic field strength and the dominant relaxation mechanism was found to be chemical shift anisotropy.

Group 14 of the periodic table is surely one of the most interesting for the NMR spectroscopist. With the exception of germanium, all the other members have favourable NMR properties: tin, silicon and lead have at least one spin $\frac{1}{2}$ isotope of good sensitivity.

Silicon and tin have been studied extensively, and several applications have been found in chemistry. Only few reports are available on germanium, which has only one magnetic isotope, ^{73}Ge , characterized by a relatively large quadrupole moment; this has limited the number of compounds studied, and only a little more data is available on lead. There is a sizeable literature on tin, beginning with the first investigation in 1961. For example, there has been extensive compilation of solution and solid-state ^{119}Sn chemical shifts and coupling constants, mainly in organometallic chemistry. These data are often useful in the determination of molecular structures, not only of small molecules but also of polymeric and cluster compounds. In particular, solution data are the main tools for gaining information on the progress of a selected reaction, on the existence of donor–acceptors and/or

solute–solvent interactions, of dissociation or auto-association, and of intramolecular coordination.

Moreover, one-dimensional (1D) and two-dimensional (2D) proton detected heteronuclear correlation NMR techniques involving ^{119}Sn and ^{207}Pb nuclei have been used for applications in organometallic NMR. In particular, the development of organometallic chemistry has been affected markedly by the ever-increasing capabilities of NMR instruments. Prominent NMR parameters such as chemical shifts, coupling constants and relaxation times have also been exploited to gain information on organo-E (E = Ge, Sn, Pb) compounds not readily available by other methods.

Properties of the Nuclei

The nuclear properties are summarized in Table 1.

Germanium possesses only one magnetic isotope, ^{73}Ge , with spin $\frac{9}{2}$. This nucleus shows a combination of properties unfavourable to magnetic resonance studies, so that only a limited range of molecules can be studied: the natural abundance is 7.76%, the gyromagnetic ratio is very small ($\gamma = -0.9332 \times 10^7 \text{ rad T}^{-1} \text{ s}^{-1}$), and the nuclear quadrupole is moderately large. The sensitivity with respect to ^1H at natural abundance and constant field is 1.08×10^{-4} . Since quadrupolar relaxation dominates, dipole–dipole relaxation and nuclear Overhauser effects (NOE) are not important and unsymmetric germanium compounds often give very broad ^{73}Ge NMR signals.

Tin possesses three magnetically active tin isotopes with spin $I = \frac{1}{2}$ (^{115}Sn , ^{117}Sn , ^{119}Sn). Two of them, ^{117}Sn

Table 1 NMR properties^a of magnetic isotopes of germanium, tin and lead

Nucleus	Spin	NA (%)	R^H	R^C	γ ($10^7 \text{ rad T}^{-1} \text{ s}^{-1}$)	Ξ (MHz)	Q (10^{-28} m^2)
^{73}Ge	$\frac{9}{2}$	7.76	1.08×10^{-4}	0.622	−0.9332	3.488 315	−0.17
^{115}Sn	$\frac{1}{2}$	0.35	1.24×10^{-4}	0.705	−8.792	32.718 780	—
^{117}Sn	$\frac{1}{2}$	7.51	3.49×10^{-3}	19.8	−9.578	35.632 295	—
^{119}Sn	$\frac{1}{2}$	8.58	4.51×10^{-3}	25.6	−10.021	37.290 662	—
^{207}Pb	$\frac{1}{2}$	22.6 ^b	2.1×10^{-3}	11.9	5.6264	20.920 597	—

^aNA is the natural abundance (%); R^H and R^C are the receptivities relative to that of ^1H and ^{13}C , respectively; γ is the gyromagnetic ratio; Ξ is the resonance frequency for the reference compound $(\text{Me})_4\text{E}$ (E = Ge, Sn or Pb) in a magnetic field for which $(\text{Me})_4\text{Si}$ has a proton resonance of 100 MHz; Q is the electric quadrupole moment.

^bVaries with sources.

(7.51%) and ^{119}Sn (8.58%), have an appreciable natural abundance and receptivities ~ 20 and 25 times greater, respectively, than that of ^{13}C . The low natural abundance makes the ^{115}Sn resonance unfavourable. The basic resonance frequencies for ^{115}Sn , ^{117}Sn , and ^{119}Sn are 98.16, 106.90, and 111.87 MHz on a spectrometer that operates at a field strength of 7.05 T with ^1H NMR at 300 MHz.

In tin NMR experiments, the negative gyromagnetic ratio can lead to disadvantageous NOE behaviour, which can be suppressed by inverse gated decoupling or by using relaxation rate enhancement additives. This problem is not present in the NMR of lead compounds: in fact ^{207}Pb , the only lead isotope with spin $\frac{1}{2}$ (the natural abundance is $\sim 22\%$ and the sensitivity to detection is 0.09% of that of the proton), has a positive gyromagnetic ratio. The maximum $^{207}\text{Pb}\{-^1\text{H}\}$ nuclear Overhauser effect is 350%.

Experimental Aspects

Samples for solution studies are prepared in the same manner as for ^1H NMR spectroscopy. In most of the experiments, the standard reference compound is the tetramethyl-E (E = Ge, Sn, Pb) derivative, although sometimes GeCl_4 and SnCl_4 are used as references in ^{73}Ge and ^{119}Sn NMR spectra, respectively. The tetramethyl-E compound can be used externally; however, on modern NMR spectrometers it is generally preferable to use a known absolute frequency.

There are great difficulties in determining the chemical shifts of ^{73}Ge nuclei by direct observation owing to its low natural abundance and receptivity and large quadrupole moment. Coupling to ^{73}Ge is rarely reported; however, if appreciable $^1\text{H}\text{--}^{73}\text{Ge}$ coupling is present, the observation of ^{73}Ge resonances can be achieved by heteronuclear double-resonance experiments. Special pulse sequences such as INEPT (insensitive nuclei enhancement by polarization transfer) which effect nuclear spin polarization transfer from nuclei of high gyromagnetic ratio (γ), usually ^1H , to nuclei of small γ , and allow dramatic increases in signal-to-noise ratio and corresponding decreases of spectral accumulation time, have been used in the study of simple symmetrical molecules.

The ^{119}Sn nucleus is generally preferred in tin NMR experiments because of its greater natural receptivity. ^{119}Sn chemical information is obtained from 1D ^{119}Sn NMR and $^nJ(^{119}\text{Sn}, ^1\text{H})$, $^nJ(^{119}\text{Sn}, ^{13}\text{C})$ and $^nJ(^{119}\text{Sn}, ^{117}/^{119}\text{Sn})$ coupling, or by using the $^1\text{H}\text{--}\{^{119}\text{Sn}\}$ heteronuclear double magnetic resonance (HDMR) method, polarization transfer techniques such as INEPT and DEPT (distortionless enhancement polarization transfer), or proton-detected heteronuclear $^1\text{H}\text{--}\{^{119}\text{Sn}\}$ correlation techniques such as HMQC (heteronuclear

multiple-quantum coherence). HMQC NMR spectroscopy can be easily applied to the structure elucidation of organotin compounds, while in those containing at least a single Sn–N bond it is possible to measure very efficiently the $J(^{119}\text{Sn}, ^{15}\text{N})$ coupling constant from ^{15}N satellites in ^{119}Sn NMR spectra by application of the Hahn-echo extended (HEED) INEPT experiment.

The magnitude and sign of $^nJ(^{119}\text{Sn}, \text{X})$ and $^nJ(^{207}\text{Pb}, \text{X})$ coupling constants are fundamental requisites for interpreting the bonding and structure in tin and lead compounds. Relative signs of the coupling constants can be obtained efficiently from 2D heteronuclear shift correlation (HETCOR) experiments. This method is helpful also in determining small long-range coupling constants (e.g. $^4J(^{117/119}\text{Sn}, ^1\text{H})$), which are normally not resolved in 1D ^1H NMR spectra.

In order to obtain highly resolved, selective solid-state information, much work has been done on solid-state ^{119}Sn and ^{207}Pb NMR using magic angle spinning (MAS) and cross-polarization (CP) methods.

Chemical Shifts

In agreement with Ramsey's theory, the variation of the 'paramagnetic term' σ_p is the dominating factor in the nuclear screening (eqn [1]) for all three elements, i.e. germanium, tin and lead.

$$\sigma = \sigma_p + \sigma_d + \sigma_n \quad [1]$$

In eqn [1] σ_d is the diamagnetic contribution to shielding; σ_n includes all diamagnetic and paramagnetic nonlocal contributions; and σ_p is a function of at least three factors: the effective nuclear charge, the p and d electron imbalance term, and the average excitation energies; σ_p and σ_d may be calculated in principle for a given system, but the theory has not yet been developed, so that this model may be applied with success only when calculating the difference in shielding in closely related compounds, whereas for heavy-atom substituents σ_p does not reflect the influence of nearest neighbours.

Germanium, tin and lead chemical shifts cover a very large range if inorganic and organometallic compounds are examined: more than 1200 ppm for ^{73}Ge , 5000 ppm for ^{119}Sn , and 12 000 ppm for ^{207}Pb . Tables 2, 3 and 4 exhibit selected ^{73}Ge , ^{119}Sn and ^{207}Pb data, all referred to (Me)₄E (E = Ge, Sn or Pb), a negative sign indicating a higher shielding or a shift to lower frequencies.

Isotope Effects

In the case of tin, the primary isotope effect (dependence of the screening upon the type of nuclide of tin investigated) should be considered. The chemical shift difference [$\delta(^{119}\text{Sn}) - \delta(^{117}\text{Sn})$] has been measured for a

number of organotin compounds in noncoordinating solvents, and in most cases the primary isotope effect is negligibly low. Secondary isotope effects are more important: for example, ^{119}Sn chemical shifts have been measured for Me_2SnH_2 , Me_2SnHD and Me_2SnD_2 and a shift of ~ 1 ppm to lower frequencies has been observed when one H is replaced by one D. The largest isotopic effect has been observed with the $[\text{SnH}_3]^-$ anion, where the ^{119}Sn chemical shift moves by 9.84 ppm on perdeuteration. The isotopic effects in the case of germanium and lead compounds have not been widely studied: however, it has been found that they are generally greater for ^{207}Pb and less for ^{73}Ge with respect to ^{119}Sn .

Solvent and Temperature Dependence of Tin, Germanium and Lead Chemical Shifts

Tin, germanium and lead chemical shifts are not very sensitive to temperature in the absence of chemical changes (e.g. autoassociation, dissociation, change in coordination number of the atom of the nucleus examined). Sometimes variations in conformational populations and electrostatic solvent-solute interactions can produce appreciable effects, and it has been found, for example,

that shielding of the ^{119}Sn nucleus generally increases roughly linearly with increasing temperature. Analogously, change in solvent, in the absence of solvent-solute chemical interactions, autoassociation or dissociation affects the tin, germanium and lead chemical shifts only slightly with respect to their chemical shift ranges.

Coordination Number Dependence of Tin, Germanium and Lead Chemical Shifts

Taking into account that relevant excitation energies are fairly constant, the paramagnetic term σ_p , which

represents the imbalance of charge, could be related to local symmetry. It has been established that an increase in coordination number produces a significant increase in the shielding of $\text{Sn}(\text{IV})$ and $\text{Pb}(\text{IV})$.

Germanium(IV) compounds have been less studied in this regard; however, they seem to show the same behaviour. For example the GeCl_4 -2,2'-bipyridine adduct [1] containing a hexacoordinate germanium has $\delta(^{73}\text{Ge}) \sim 340$ ppm upfield shifted with respect to the four-coordinate compound GeCl_4 .

[1] $\delta(^{73}\text{Ge}): -313.7$ ppm

The knowledge of $\delta(^{119}\text{Sn})$ chemical shifts is very important for predicting the geometry of coordination polyhedra of tin compounds in solution. In the case of tetravalent tin compounds, an increase in tin coordination

number from four to five corresponds to an increase in tin shielding by ~ 150 – 200 ppm. Similar increases are generally associated with six and seven coordination. The $\delta(^{119}\text{Sn})$ for $\text{PhSn}(\text{edtc})_2\text{Br}$ [2], a hexacoordinate pseudo-octahedral tin complex, is -704.1 ppm, whereas $\delta(^{119}\text{Sn})$ for $\text{PhSn}(\text{edtc})_3$ [3] in which the central Sn has coordination number seven and the shape is distorted pentagonal bipyramidal is -806.5 ppm.

[2] $\delta(^{119}\text{Sn}): -704.1$ ppm[3] $\delta(^{119}\text{Sn}): -806.5$ ppm

The ^{119}Sn chemical shift also provides effective means of studying covalent solute-solvent interaction, auto-association, dissociation, and intramolecular coordination. For example, the ^{119}Sn chemical shift is nearly concentration independent when tin(IV) and organotin compounds such as Me_2SnCl_2 are dissolved in non-coordinating solvents such as chloroform or benzene (Figure 1). On the other hand, when Me_2SnCl_2 is dissolved in various donor solvents such as acetonitrile, pyridine and dimethyl sulfoxide, the chemical shift shows dependence on the concentration.

The magnitude of the chemical shift can permit determination of association constants between the tin compound and the solvent. For example, formation of a 1:1 complex of trimethyltin chloride in dimethyl sulfoxide may be written as in eqn [2].

The equilibrium constant can be calculated from the concentration dependence found for ^{119}Sn chemical shifts (eqn [3]):

$$K = \frac{k_1}{k_2} = \frac{\delta_o(\delta_c - C\delta_o)}{\delta_o^2(1 - C) + C\delta_o^2 - \delta_o\delta_c} \quad [3]$$

where δ_o is the ^{119}Sn chemical shift for $\text{Bu}_3^{\text{n}}\text{SnCl}$, δ_c is the ^{119}Sn chemical shift for the $\text{Bu}_3^{\text{n}}\text{Sn}(\text{DMSO})\text{Cl}$, and C is the molar fraction of $\text{Bu}_3^{\text{n}}\text{SnCl}$.

Figure 1 ^{119}Sn NMR spectra of Me_2SnCl_2 in chloroform, benzene, acetone, methanol, dimethyl sulfoxide and acetonitrile (concentration $\sim 40 \text{ mg ml}^{-1}$).

This type of behaviour is also displayed by lead and organolead compounds; the changes in $\delta(^{207}\text{Pb})$ are generally larger than changes in $\delta(^{119}\text{Sn})$: for example, the ^{207}Pb chemical shift for derivative $\text{Pb}(\text{Ph})_2(\text{O}_2\text{CMe})_2$ is -688 ppm in CHCl_3 and -859 ppm in pyridine.

Organotin(IV) thiolates show a low tendency to form complexes with molecules of coordinating solvent. However, it has been observed that although the $\delta(^{119}\text{Sn})$ for the organotin(IV) thiolate compound $\text{Bu}_3\text{Sn}[\text{S}(\text{1-C}_{10}\text{H}_7)]$ [4] is concentration independent in noncoordinating

solvent, the variation of $\delta(^{119}\text{Sn})$ with temperature in pyridine (Py) is at first a sigmoidal curve which is typical of the equilibrium (eqn [4]).

[4] $\delta(^{119}\text{Sn})$ in CDCl_3 : 89.1 ppm

In several organometal derivatives, changes in the coordination number can arise from self-association, as in the case of organotin alkoxides. This self-association depends on steric and electronic effects and it can be studied with ^{119}Sn NMR. Several $\text{R}_{4-n}\text{Sn}(\text{OR}')_n$ compounds exhibit values of chemical shifts suggesting self-association as neat liquid or in noncoordinating solvents. For example, butyltin(IV) trialkoxides with an unbranched alkoxy group, such as $\text{BuSn}(\text{OMe})_3$, [5], are six-coordinate at room temperature, the association presumably involving octahedral structures with both bridging and nonbridging alkoxy oxygen atoms. Isopropoxy groups on tin, for example in [6], increase the steric effect and inhibit six-coordination. At room temperature, the chemical shift is typical of an essentially five-coordinate situation.

[5]

[6]

Effective Nuclear Charge and Presence of Low-Lying Excited States

Electronegative substituents generally lead to higher-frequency germanium, tin and lead chemical shifts. The effect of ligand electronegativity can be illustrated by the changes of ^{119}Sn chemical shifts along the series $\text{R}_n\text{SnCl}_{4-n}$ (R = alkyl or aryl) as the value of n changes

from 2 to 0 (Figure 2a). However, the plot of the $\delta(^{119}\text{Sn})$ for the compounds $\text{R}_n\text{SnCl}_{4-n}$ (R = alkyl or aryl; n = 0, 1, 2, 3 or 4) in Figure 2b, indicates clearly that there are no obvious general relationships between $\delta(^{119}\text{Sn})$ and the ligand electronegativity. The U-shape trend is usually attributed to change in the paramagnetic term due to p electron imbalance, generally maximum at n = 2.

The ^{73}Ge chemical shift of GeCl_4 , GeBr_4 , GeI_4 and the mixed tetrahalogermanes is not a linear function of halogen coordination but is consistent with the pattern of nuclear shielding established for halogens bonded to main-group elements: as expected, the nuclear shielding increases in the order $\text{Cl} < \text{Br} < \text{I}$.

The ^{119}Sn and ^{207}Pb chemical shifts follow the same trend shown by ^{73}Ge , but the larger lead and tin shift range allows a clearer distinction between closely related species (Figure 3).

In a series of methylvinylgermanes, the ^{73}Ge chemical shifts were compared with those of the corresponding methylvinylsilanes, and the correlation $\delta(^{73}\text{Ge}) = 1.96 \delta(^{29}\text{Si}) + 2.37$ was found. It has been observed that the magnitude of the chemical shift cannot be simply attributed to the electron densities, but relative contributions of the diamagnetic and paramagnetic terms to the ^{73}Ge chemical shift should be considered.

From a comparison between ethylvinylgermanes and ethynylstannanes, a similar linear correlation $\delta(^{73}\text{Ge}) = 0.481 \delta(^{119}\text{Sn}) - 0.892$ was obtained.

Several studies have been made to evaluate the effects of the paramagnetic circulation of charge: in the monomeric bis[*N,N*-bis(trimethylsilyl)amino]-tin(II) compound [7], it has been found that circulation of charge from the trigonal plane into the underoccupied tin p_π orbitals deshields the tin atoms and produces a strong high-frequency shift (+776 ppm in C_6D_6) of the ^{119}Sn resonance. On the other hand, MO calculations indicate in monomeric tin(II) compounds such as stannocene, $(\text{C}_5\text{H}_5)_2\text{Sn}$ [8], a highly shielded tin atom (−2199 ppm in C_6H_{12}) as a consequence of an inefficient paramagnetic charge circulation due to the high LUMO energy of this molecule.

[7] $\delta(^{119}\text{Sn})$: +776 ppm

[8] $\delta(^{119}\text{Sn})$: −2199 ppm

When tin is bonded to transition metals, large ^{119}Sn chemical shift ranges have been found that cannot be explained in terms of simple inductive and coordination number effects. The shielding could be interpreted in terms of $d_\pi-d_\pi$ overlap and the effect on the average excitation energy.

Effects of Interbond Angles at the Metal Atoms

Changes in the bond angles in molecules in which the metal atom is a part of a ring system generally effect anomalous shifts of the resonances with respect to those found in analogous acyclic molecules. This is shown, for example, with tin–sulfur and lead–sulfur and with tin–carbon and lead–carbon bonds. A reduction of the cyclic

interbond angles at the metal in five-membered rings generally decreases shielding. ^{119}Sn NMR data can be used to distinguish between six-membered and five-membered cyclic compounds: the $\delta(^{119}\text{Sn})$ for compound [9] is -42.5 ppm, whereas that for the five-membered derivative [10] it is $+53.5$ ppm.

[9] $\delta(^{119}\text{Sn})$: -42.5 ppm

[10] $\delta(^{119}\text{Sn})$: $+53.5$ ppm

Other Substituent Effects

In the unassociated tin compounds $\text{R}_{4-n}\text{SnX}_n$ ($n=0-4$), as the electron-releasing power of the organic group R increases, the tin atom is generally more shielded and the $\delta(^{119}\text{Sn})$ moves to a higher field. This high-field shift, which cannot be explained in terms of $p_\pi-d_\pi$ bonding between the π electron of the electron negative groups and the unfilled 5d orbital of the tin atom, is probably due to ring current effects by the π electron and/or a finite contribution to the shift from the diamagnetic term.

The values of the $\delta(^{119}\text{Sn})$ chemical shift of diphenyltin(IV), dibenzyltin(IV) and di-*n*-butyltin(IV) compounds exhibit a good mutual correlation which can be expressed as in eqn [5].

$$\delta(^{119}\text{Sn})[\text{R}_2^* \text{Sn}] = a\delta(^{119}\text{Sn})[\text{R}_2^\# \text{Sn}] + b \quad [5]$$

where $[\text{R}_2^* \text{Sn}]$ and $[\text{R}_2^\# \text{Sn}]$ represent pairs of diorganotin(IV) compounds with different organic substituents, and a and b represent the slope and the intercepts of the linear correlation, respectively.

In some cases it has also been observed that a remote substituent in molecules in which direct π transmission

mechanisms are prohibited can have a very strong influence on the nuclear shielding: for example, the ^{119}Sn substituent chemical shift (SCS) for derivative [11] (relative to parent molecule) [12], which is due to both 'polar-field' and 'residual contribution' where the latter is probably due to 'through-bond' and/or 'through space electron delocalization', is very sensitive to polar substituent influences, like that derived from iodide groups.

[11] $\delta(^{119}\text{Sn})$: +14.54 ppm

[12] $\delta(^{119}\text{Sn})$: +0.46 ppm

Coupling Constants

The valence electron-mediated nuclear spin-spin couplings, $J(^{73}\text{Ge}, \text{X})$, $J(^{117}\text{Sn}, \text{X})$, $J(^{119}\text{Sn}, \text{X})$ and $J(^{207}\text{Pb}, \text{X})$, are dominated by the 'Fermi contact' term arising from the interaction of the nuclear spin magnetic dipole with the electron spin, which has a finite density at the nucleus. If the contact term is expressed with Pople and Santry's MO treatment and it is permissible to use the mean electronic excitation energy approximation, the coupling constants can be related to the hybridization (i.e. 's' electron density) and effective nuclear charge of the atoms participating in the bond. This implies that the parameters $J(\text{E}, \text{X})$ ($\text{E} = \text{Ge}, \text{Sn}$ or Pb) are useful in the discussion of the structure and bonding.

The reduced couplings $K(\text{Ge}, \text{X})$ and $K(\text{Sn}, \text{X})$ are of opposite sign with respect to $J(\text{Ge}, \text{X})$ and $J(\text{Sn}, \text{X})$, respectively, owing to the negative magnetogyric ratios of ^{73}Ge and $^{115/117/119}\text{Sn}$.

In the case of $\text{X} = ^1\text{H}$, ^{19}F , ^{31}P , highly abundant spin- $\frac{1}{2}$ nuclei, the $^nJ(\text{E}, \text{X})$ data are obtained conveniently from the X atom NMR spectra, whereas in the case of couplings with rare spin- $\frac{1}{2}$ nuclei ($\text{X} = ^{13}\text{C}$, ^{29}Si , ^{15}N), the $^nJ(\text{E}, \text{X})$ can be obtained also from E NMR spectra by using Hahn-echo extended pulse sequences. In tin derivatives, in the case of couplings to quadrupolar X nuclei ($\text{X} = ^{11}\text{B}$, ^{14}N), it frequently happens that splitting due to $^{119}\text{Sn}-\text{X}$ coupling cannot be detected as a consequence of fast quadrupolar relaxation of X. The magnitude of J can be obtained from eqn [6].

$$J(\text{Sn}, \text{X}) = \frac{\pi}{2} \left(\frac{3}{T_2^{\text{SC}}(^{119}\text{Sn}) S_x(S_x + 1) T_{\text{(x)}}^{\text{Q}}} \right)^{1/2} \quad [6]$$

where S_x is the spin I of the quadrupolar nucleus, $T_2^{\text{SC}}(^{119}\text{Sn})$ is the transverse scalar relaxation time, and $T_{\text{(x)}}^{\text{Q}}$ is the quadrupolar relaxation time.

Table 5 Some representative spin coupling involving ^{73}Ge

Compound	Coupling constant	(Hz)
GeH_4	$^1J(^{73}\text{Ge}, ^1\text{H})$:	− 97.6
Me_4Ge	$^1J(^{73}\text{Ge}, ^{13}\text{C})$:	− 18.7
GeF_4	$^1J(^{73}\text{Ge}, ^{19}\text{F})$:	− 97.6
Me_4Ge	$^2J(^{73}\text{Ge}, ^1\text{H})$:	+ 3.0
$(\text{MeO})_4\text{Ge}$	$^3J(^{73}\text{Ge}, ^1\text{H})$:	− 1.9
$(\text{MeS})_4\text{Ge}$	$^3J(^{73}\text{Ge}, ^1\text{H})$:	− 2.5

The most correct way to obtain the sign of the coupling of $J(\text{E}, \text{X})$, which is helpful in the discussion of the nature of chemical bonding, is based on the analysis of an energy level diagram that describes the interaction in a spin system. In a system containing at least three different magnetically active nuclei (E , A and X), two of them are defined as active spins, whereas the other is the passive one. If the relative signs of the coupling $J(\text{E}, \text{A})$ and $J(\text{E}, \text{X})$ and the absolute sign of one of these two are known, it is possible to determine the absolute sign of the other.

Spin couplings involving ^{73}Ge have been generally reported only in highly symmetrical compounds; **Table 5** gives a selection of the values of the coupling constants in germanium compounds of tetrahedral symmetry. The signs of these coupling constants are indicated only by comparison with those of similar group 14 element compounds and not by double resonance experiments.

One-Bond Couplings

In the case of couplings with electropositive elements, the one-bond reduced coupling constants show the trend $^1K(\text{Ge}, \text{X}) < ^1K(\text{Sn}, \text{X}) < ^1K(\text{Pb}, \text{X})$. In fact, the increase of $^1K(\text{E}, \text{X})$ with increasing size of E corresponds to the change of valence electron densities $\Psi_{\text{M}}(\text{O})^2$. This relationship is not valid when X is a less electropositive or more polarizable atom. **Table 6** gives a selection of values of a one-bond coupling constant involving ^{119}Sn and ^{207}Pb .

$^1J(\text{E}, ^1\text{H})$

Very few one-bond coupling constants between ^{119}Sn or ^{207}Pb and H have been measured. This is in part due to the instability and the difficulty of preparing suitable species. Limited data are available for ^{119}Sn and indicate that the magnitude of the $^1J(^{119}\text{Sn}-\text{H})$ in $\text{R}_{4-n}\text{SnH}_n$ increases with n when $\text{R} = \text{alkyl}$ and decreases with n when $\text{R} = \text{phenyl}$, owing to greater electronegativity of phenyl with respect to alkyl groups. In SnH_3^- the presence of an electron lone pair at tin leads to a very low s character for hybrid orbitals in $\text{Sn}-\text{H}$ bonds, and hence to a very small magnitude of coupling.

$^1J(E, ^{13}\text{C})$

Owing to the large number of organolead and organotin species, there is a sizeable literature of data on $^1J(E, ^{13}\text{C})$ coupling constants ($E = ^{119}\text{Sn}$ or ^{207}Pb).

The magnitude of $^1J(^{119}\text{Sn}, ^{13}\text{C})$ organotin compounds has been related quantitatively to the C–Sn–C bond angles. A simple linear relationship between $^1J(^{119}\text{Sn}, ^{13}\text{C})$ coupling constants of a group of dimethyltin(IV) compounds and their C–Sn–C angle (θ) has been found on the basis of the analysis of a large set of experimental data (eqn [7]).

$$|^1J(^{119}\text{Sn}, ^{13}\text{C})| = (10.7 \pm 0.5)\theta - (778 \pm 64) \quad [7]$$

A similar relation has been described for di-*n*-butyltin(IV) compounds (eqn [8]).

$$|^1J(^{119}\text{Sn}, ^{13}\text{C})| = (9.99 \pm 0.73)\theta - (746 \pm 100) \quad [8]$$

and for tetra-, tri- and diphenyltin(IV) compounds (eqn [9])

$$|^1J(^{119}\text{Sn}, ^{13}\text{C})| = (15.56 \pm 0.84)\theta - (1160 \pm 101) \quad [9]$$

Equation [7] is not valid for cyclic methyltin(IV) compounds.

The sign of $^1J(^{119}\text{Sn}, ^{13}\text{C})$ is generally negative for all tetraorganotin(IV) compounds, whereas $^1J(^{207}\text{Pb}, ^{13}\text{C})$ is positive for tetraorganolead(IV) derivatives.

In R_4Sn ($\text{R} = \text{alkyl}$) compounds, $^1J(^{119}\text{Sn}, ^{13}\text{C})$ decreases in magnitude with increasing chain length and branching. It has also been found that in the tetraorganotin derivatives the magnitude of $^1J(^{119}\text{Sn}, ^{13}\text{C})$ increases with change of the hybridization of the carbon atoms from sp^3 to sp .

The replacement of alkyl groups with electronegative substituents causes an increase in the magnitude of $^1J(^{119}\text{Sn}, ^{13}\text{C})$ as the result of a greater s character in the Sn–C hybrid orbital.

Very small values of $^1J(^{119}\text{Sn}, ^{13}\text{C})$ are found in cyclopentadienyltin(IV) compounds owing to the low carbon s character in the pentahapto link to tin, whereas the small values in allyl- and benzyltin(IV) compounds may be ascribed to σ – π conjugative connection of the polarized $\sigma(\text{Sn}–\text{C})$ bond with the adjacent π electron system.

As in the case of the $\delta(^{119}\text{Sn})$ chemical shift, moderate linear correlations have been found between the values of triphenyltin(IV) compounds and those of analogous triorganotin compounds R_3SnX ($\text{R} = \text{Bu}^n, \text{Bz}, \text{Vi}$) which can be expressed as eqn [10]

$$^1J(^{119}\text{Sn}, ^{13}\text{C})(\text{Ph}_3\text{Sn}) = a \ ^1J(^{119}\text{Sn}, ^{13}\text{C})(\text{R}_3\text{Sn}) + b \quad [10]$$

a and b being slope and intercepts, respectively.

$^1J(E, X)$ ($X = ^{15}\text{N}, ^{31}\text{P}, ^{19}\text{F}, ^{119}\text{Sn}, ^{207}\text{Pb}$)

Several studies have been carried out on the bis(amino)stannylenes, where the coupling constants $^1J(^{119}\text{Sn}, ^{15}\text{N})$ are generally large and negative in accordance with a Ψ -pseudotrigonal-bipyramidal structure, whereas in stannylphosphane compounds $^1J(^{119}\text{Sn}, ^{31}\text{P})$ are generally positive and strongly dependent not only on changes in hybridization and substituent electronegativity, but also on s-overlap integral.

It has been found that the values of $^1K(^{119}\text{Sn}, ^{31}\text{P})$ for $(\text{R}_3\text{Sn})_3\text{P}$ derivatives become less negative if the phosphorus lone electron pair is used in metal complexation.

$^1J(^{119}\text{Sn}, ^{19}\text{F})$ coupling constants are reported for hydroxo- and peroxotin(IV) fluoro complexes [13] and [14] and for $[\text{SnF}_6]^{2-}$ species. Their magnitude is strongly dependent on the stereochemistry.

[13]

$^1J(^{119}\text{Sn}, ^{19}\text{F})$:
1820 Hz (*trans*-OH)
1518 Hz (*trans*-F)

[14]

$^1J(^{119}\text{Sn}, ^{19}\text{F})$:
2064 Hz (*trans*-OOH)
1692 Hz (*trans*-F)

Several negative terms contribute to the extent of $^1K(\text{E}, ^{19}\text{F})$ so that no values are known for lead–fluorine and only a few tin–fluorine couplings have been reported.

$^1J(^{119}\text{Sn}, ^{119}\text{Sn})$ values are generally positive and show clear dependence upon tin hybridization. When very bulky substituents are on tin atoms, the tin–tin *s*-overlap integral is small, whereas the mutual polarizability term changes sign, so that very small or negative $^1J(^{119}\text{Sn}, ^{119}\text{Sn})$ values are found. Large values of $^1J(^{119}\text{Sn}, ^{119}\text{Sn})$ have been detected in tin–tin complexes containing electronegative substituents or characterized by greater coordination number.

$^1J(^{119}\text{Sn}, ^{207}\text{Pb})$ values are normally negative and often of very small magnitude owing to reduced lead–tin *s*-overlap.

$^1J(^{207}\text{Pb}, ^{207}\text{Pb})$ are positive, and values are also very small for the same reason: lead–lead compounds are in fact easily dissociated in solution owing to small lead–lead overlap.

$^1J(\text{E}, \text{Transition Metal})$

Many tin–transition metal coupling constants are known owing to the ease of obtaining [(SnCl₃)–transition metal] derivatives. The $^1J(^{119}\text{Sn}, \text{transition metal})$ values are generally large and are used to characterize complexes having tin–metal bonds also in solution. It has been observed that in square planar Pt(II) complexes [15] and [16], the magnitude of the $^1J(^{195}\text{Pt}, ^{119}\text{Sn})$ coupling constants depends on the magnitude of the *trans* effect of the respective substituent.

[15] $^1J(^{195}\text{Pt}, ^{119}\text{Sn})$: 16 321 Hz [16] $^1J(^{195}\text{Pt}, ^{119}\text{Sn})$: 28 052 Hz

Geminal Coupling Constants, $^2J(\text{E}, \text{Y})$

The geminal coupling constants $^2J(\text{E–X–Y})$ (Table 7) are sensitive not only to the factors reported for one-bond couplings, but also to the nature of the intervening atom X, to the metal–X–Y bond angle, to the stereochemistry of the molecule and finally to the nature of other substituents.

Table 7 Selected geminal coupling constants $^2J(\text{E}, \text{Y})$

$^2J(\text{E–X–}^1\text{H})$

Several data have been reported, in particular for X = C. There is a linear relationship between $^2J(^{119}\text{Sn}, ^1\text{H})$ and $^2J(^{207}\text{Pb}, ^1\text{H})$ and also between $^2J(^{119}\text{Sn}, ^1\text{H})$ and $^1J(^{119}\text{Sn}, ^{13}\text{C})$ in related methyltin(IV) and methyllead(IV) derivatives. In several dimethyltin(IV) complexes the values of $^2J(^{119}\text{Sn}, ^1\text{H})$ can be used to calculate the bond angles C–Sn–C in solution (eqn [11]).

$$(\text{angle C – Sn – C}) = 0.0161[{}^2J(^{119}\text{Sn}, ^1\text{H})_{\text{Me}}]^2 + 133.4 \quad [11]$$

The sign of $^2J(^{119}\text{Sn}, ^1\text{H})$ is generally positive. Exceptionally the coupling can be negative, as in Me₃Sn[–] and diorganostannylenes, whereas the $^2J(^{207}\text{Pb}, ^1\text{H})$ are negative and normally greater than $^2J(^{119}\text{Sn}, ^1\text{H})$ in related compounds. The magnitude of $^2J(\text{E–C–}^1\text{H})$ increases with increasing coordination number on the metal. $^2J(^{207}\text{Pb}, ^1\text{H})$ values are generally less sensitive than $^2J(^{119}\text{Sn}, ^1\text{H})$ to structural geometrical differences. In several octahedral and square planar complexes, the magnitude of the $^2J(^{119}\text{Sn–X–}^1\text{H})$ across a transition metal X can be used to distinguish the *trans* (compound [17]) and *cis* positions (compound [18]) of Sn and H.

[17] $^2J(^{119}\text{Sn}, ^1\text{H})$: 1740 Hz

[18] $^2J(^{119}\text{Sn}, ^1\text{H})$: ± 27 Hz

$^2J(E-X-^{13}C)$

The $^2J(^{119}\text{Sn}-X-^{13}C)$ couplings are generally small and positive in aliphatic and tetracoordinate tin derivatives, whereas they are large and negative in compounds containing an $\text{Sn}-C_{\text{olefinic}}-C$ bond and close to 0 in compounds containing an $\text{Sn}-C=C$ bond. In some cases the values are exceptionally large, as in $\text{Sn}(C\equiv C\text{Bu})_4$.

Other Geminal Couplings

The couplings best studied are those involving ^{119}Sn , ^{117}Sn , ^{19}F and ^{31}P . For example, in bis(triorganotin)oxides the geminal couplings $^2J(^{119}\text{Sn}, ^{119}\text{Sn})$ indicate a linear structure in solution. The $^2J(^{119}\text{Sn}-X-^{119}\text{Sn})$, where the X intervening atom is a transition metal, show a strong dependence on the geometry and on the nature of other ligands on the metal or on tin atoms: for example, the $^2J(^{119}\text{Sn}-\text{Pt}-^{119}\text{Sn})$ is 2601 Hz in *cis*-[PtCl₂(Cl₃Sn)₂] compound [19] and 36 286 Hz in *trans*-[PtCl₂(Cl₃Sn)₂] (compound [20]).

[19] $^2J(^{119}\text{Sn}, ^{119}\text{Sn})$: 2601 Hz [20] $^2J(^{119}\text{Sn}, ^{119}\text{Sn})$: 36 286 Hz

A similar geometrical dependence has been shown by $^2J(^{119}\text{Sn}-\text{Pt}-^{31}\text{P})$. Two-bond couplings involving ^{19}F are detected in $(\text{CF}_3)_4\text{Ge}$ (26.3 Hz), in $(\text{CF}_3)_4\text{Sn}$ (531 Hz) and also in the organolead derivatives $(\text{Me})_3\text{Pb}(\text{CF}_3)$ (240 Hz) and $(\text{Me})_2\text{Pb}(\text{CF}_3)_2$ (379 Hz), which show a strong dependence on the effective nuclear charge.

Vicinal and Long-Range Coupling Constants, $^nJ(E, Y)$ ($n \geq 3$)

Many vicinal coupling constants (Table 8) are known, with different combinations of intervening atoms. In most cases the $^3J(^{119}\text{Sn}, X)$ data are dependent on the respective dihedral angles and follow a Karplus-type relationship. The sign of $^3J(^{119}\text{Sn}, ^1\text{H})$ and $^3J(^{119}\text{Sn}, ^{13}\text{C})$ is negative and the magnitudes of $^3J(^{119}\text{Sn}, ^1\text{H})$ and $^3J(^{119}\text{Sn}, ^{13}\text{C})$ are usually greater than that of $^2J(^{119}\text{Sn}, ^1\text{H})$ and $^2J(^{119}\text{Sn}, ^{13}\text{C})$, respectively.

In several olefinic compounds it has been observed that $^3J(^{119}\text{Sn}, ^{13}\text{C})_{\text{trans}}$ is greater than $^3J(^{119}\text{Sn}, ^{13}\text{C})_{\text{cis}}$. The magnitude of $^3J(^{119}\text{Sn}, ^1\text{H})$ and $^3J(^{119}\text{Sn}, ^{13}\text{C})$ is strongly dependent on the nature of the substituents, an increase being observed in the presence of electro-positive substituents on the $C=C$ double bond.

$^3J(^{119}\text{Sn}, ^{119}\text{Sn})$ often behaves in a similar manner to $^3J(^{119}\text{Sn}, ^1\text{H})$ and $^3J(^{119}\text{Sn}, ^{13}\text{C})$. For example, $^3J(^{119}\text{Sn}, ^{119}\text{Sn})$ is 491 Hz in *cis*- and 1012 Hz in *trans*- $\text{Me}_3\text{SnCH}=\text{CHMe}_3$, respectively.

Table 8 Selected vicinal and long-range coupling constants $^nJ(E, Y)$

Compound	Y	E	n	$^nJ(E, Y)$ values (Hz)
Et_4Sn	^1H	^{119}Sn	3	-71.2

$(4-\text{MeC}_6\text{H}_4)_4\text{Pb}$	^1H	^{207}Pb	6	5.4
$\text{Me}_3\text{PbPbMe}_3$	^1H	^{207}Pb	3	+22.9
$(\text{Me}_3\text{CCH}_2)_4\text{Pb}$	^1H	^{207}Pb	4	5.3

CHSnMe_3 , respectively. An exceptionally large value of $^3J(^{119}\text{Sn}, ^{119}\text{Sn})$ is found for the derivative [21] owing to an additive coupling pathway across the Pt-Pt bond, whereas very small $^3J(^{119}\text{Sn}, ^{119}\text{Sn})$ are observed across the $C\equiv C$ bond.

[21] $^3J(^{119}\text{Sn}, ^{119}\text{Sn})$: 25430 Hz

Several long-range coupling constants (Table 8) are reported for many different X nuclei, but they have not been systematically studied. Analogously to $^nJ(^1\text{H}, ^1\text{H})$ ($n \geq 3$), the $^nJ(E, Y)$ couplings are best transferred by π system or by $\sigma-\pi$ interaction.

Relaxation Behaviour

The dominant relaxation mechanism for ^{73}Ge is quadrupolar, and it is possible to obtain T_1 directly from the line width.

The tin and lead compounds so far described are generally small, highly symmetrical molecules in which the spin-rotation (SR) mechanism is important.

In the tetrahalogermanes GeX_4 ($\text{X} = \text{Cl}, \text{Br}$ or I), T_1 is almost exclusively dominated by the quadrupole relaxation mechanism, while T_2 is dominated by the combination of the scalar coupling and the quadrupole relaxation mechanism in the high-temperature region. The contribution of scalar coupling to the relaxation mechanism decreases in the order

Relaxation studies on liquid tetrahalotin(IV) compounds, carried out to determine temperature and field dependences of relaxation, indicated that T_1 for SnCl_4 , SnMe_4 and SnMeCl_3 is dominated by a spin-rotation mechanism, while both scalar (SC) and spin-rotation (SR) mechanisms contribute to T_1 for SnBr_4 and SnI_4 . On the other hand, T_2 for SnCl_4 , SnBr_4 and SnI_4 is scalar dominated. When the molecules have hydrogens directly linked to tin, $^{119}\text{Sn}/^1\text{H}$ dipolar relaxation is significant.

In the derivative $\text{Bu}_3\text{SnSnBu}_3$, the relaxation is about 75% T_1^{DD} .

In a 3 M solution of $\text{Pb}(\text{ClO}_4)_2$, the dominant T_1 relaxation is spin rotation. At higher concentration, CSA (chemical shift anisotropy) and dipolar contributions are also present and important. SC and SR mechanisms contribute to T_1 for neat PbCl_4 . CSA is significant in PbMe_3Cl in DMSO, which probably coordinates the lead atom.

Applications

Solid-State NMR

Solution and solid-state structures of metal and organo-metal derivatives are often not identical. High-resolution solid-state NMR experiments on metallic and organo-metallic compounds are important tools for bridging the information gap between X-ray diffraction results and solution-state NMR data. Until now, most of the high-resolution work in tin(IV), organotin(IV), lead and organolead(IV) chemistry has dealt with the combined use of cross-polarization and magic angle spinning (CP/MAS) techniques. The experimental conditions for ^{119}Sn and ^{207}Pb spectra are different from those usually employed for ^{13}C CP/MAS spectra of organic and organometallic compounds owing to smaller gyromagnetic ratios and larger shielding anisotropies. The usual CP/MAS situation for ^{119}Sn and ^{207}Pb is the presence of only a few resonances with large shielding anisotropies, so that it is very easy to determine shielding tensor components from one-dimensional CP/MAS spectra.

An example of application of CP/MAS is the $(\text{Bu}_3\text{Sn})_2\text{CO}_3$ derivative [22]: the ^{119}Sn solution spectrum gives only one resonance at +101.7 ppm, in accordance with a monomeric tetracoordinated tin atom. The crystal structure of this compound clearly indicates a two-Sn

environment: a polymeric chain of trigonal-bipyramidal *trans*- R_3SnO_2 units linked to each other via bridging carbonate anions and tetrahedral R_3SnO units bonded to the third oxygen atom of the CO_3^{2-} bridging group. In the ^{119}Sn CP/MAS spectrum, the presence of both tin fragments, a and b, is well resolved.

CP/MAS NMR spectra are also used to clarify the controversial view of the structures of R_2SnX_2 and R_3SnX species in the solid and solution state: for example, the tricyclohexyltin hydroxide, which is a linear polymer in the solid state ($\delta = -217$ ppm) is monomeric in solution ($\delta = +11.6$ ppm). The diorganotin derivatives, which are monomeric in both phases, exhibit very similar shifts in both ^{119}Sn CP/MAS and ^{119}Sn solution NMR spectra. Small chemical shifts are observed in diorganotin and triorganotin derivatives weakly associated in the solid state and not associated in solution.

The CP/MAS NMR technique is also useful for investigating dynamic processes in solids such as re-orientational processes and structural phase transitions: an example of solid-state phase transition monitored by variable temperature ^{119}Sn CP/MAS is given by $\text{Me}_3\text{Sn}-\text{C}\equiv\text{C}-\text{C}\equiv\text{C}-\text{SnMe}_3$, for which a structural phase change occurs in the temperature range 232–248 K.

Other Applications

The ^{73}Ge NMR chemical shifts of several methyl- and phenyl-substituted germacyclohexanes have been

determined, and it has been shown that the chemical shifts are very sensitive to steric effects and can provide a useful tool for the conformational analysis of organo-germanium compounds.

The progress of reactions involving tin and lead compounds can readily be monitored by ^{119}Sn and ^{207}Pb NMR. For example, the various products derived from the 1,1-organoboration of 1-alkynyltin compounds can be easily identified by ^{119}Sn NMR, compounds [23, 24, 25].

The content of complex reaction mixtures can be also analysed: for example, several species and intermediates are detectable in exchange reactions by ^{119}Sn NMR techniques, e.g. compounds in the chemical reaction eqn [12] above.

1D and 2D ^1H - ^{119}Sn HMQC experiments are useful in the investigation of weak coordination in functionalized triphenylvinyltin(IV) compounds of the type $\text{Ph}_3\text{Sn}-\text{CH}=\text{CH}-\text{C}(\text{OH})\text{RR}'$.

The HMQC technique is widely employed in the study of the condensation product of salicylaldehyde ($o\text{-HO}-\text{N}=\text{CH}-\text{C}_6\text{H}_4-\text{OH}$) with di-*n*-butyl oxide, which in solution exists as a mixture of several coordination complexes such as [26]. In this case, two-dimensional ^1H - ^{119}Sn HMQC spectroscopy yields essential data for the structure elucidation of most of these complexes and also of the transient species, and allows several correlations between geometric parameters and $J(^{119}\text{Sn}, ^1\text{H})$ to be established.

σ_p	paramagnetic contribution to total nuclear screening

Introduction

NMR spectroscopy for this group of metals is dominated by the three nuclei: ^{183}W , ^{195}Pt and ^{199}Hg . Each of these will be dealt with in turn, followed by brief mention of other nuclei with non-zero values of the nuclear spin quantum number, I .

Tungsten, ^{183}W

The only tungsten isotope with a non-zero value of I is ^{183}W , $I = \frac{1}{2}$, (14.4% natural abundance). Its receptivity relative to that of ^1H is low (1.06×10^{-5}). Its resonance frequency in a magnetic field of 2.35 T, where protons resonate at 100 MHz, is 4.17 MHz. This nucleus is radioactive, an α -particle emitter with a long half-life ($> 1 \times 10^{17}$ y). ‘Satellite’ peaks from coupling with ^{183}W are readily observed in the ^{31}P NMR spectra of tertiary phosphine complexes, the ^1H NMR spectra of hydrides, the ^{19}F NMR spectra of fluoro complexes and the ^{13}C NMR spectra of carbonyl complexes. The earliest measurements of tungsten chemical shifts were indirect measurements through INDOR (internuclear double resonance) experiments. Direct measurement is now commonplace, but large sensitivity enhancements are possible with two-dimensional indirect spectroscopy, using the highly receptive 100% abundant nuclei ^{31}P , ^1H or ^{19}F .

A solution of $\text{Na}_2[\text{WO}_4]$ (1 M in D_2O , pD 9) is now accepted as the standard reference for ^{183}W NMR in preference to WF_6 . Relaxation times for ^{183}W are frequently long. Since a major relaxation mechanism is through chemical shift anisotropy (CSA), shorter, more favourable relaxation times are obtained when the environment about the tungsten nucleus is less symmetric. Addition of a paramagnetic substance, such as $[\text{Cr}(\text{acac})_3]$, can be used to shorten relaxation times

which are inconveniently long. The tungsten chemical shift is very sensitive to the environment about the nucleus. The overall range is large (~ 6000 ppm). Shifts for some representative compounds are given in Table 1.

Variations in chemical shifts for heavy atom nuclei are dominated by changes in σ_p , the paramagnetic contribution to total nuclear screening. For a transition metal complex, a simplified expression for σ_p is

$$\sigma_p \propto -(r^{-3}) \sum_j^{\text{occ}} \sum_k^{\text{unocc}} (E_k - E_j)^{-1} C \quad [1]$$

where r is an average distance of valence d-electrons from the nucleus, E_k and E_j are energies of unoccupied and occupied molecular orbitals, respectively, and C is a sum containing the coefficients of the metal s, p and d orbitals used in the summation to develop the various molecular orbitals. It will be noted that the tungsten nucleus in the series $[\text{W}(\text{CO})_3(\text{Cp})\text{X}]$ becomes progressively more shielded as the halide is changed from chloride to bromide to iodide, which is the ‘normal halide dependence’ order for transition metal complexes. This is opposite to the order expected from the effect of X^- on

Table 1 ^{183}W chemical shifts for some representative compounds

Compound	δ_{W} (ppm)
W(0)	
W(CO) ₆	– 3505
W(CO) ₅ (PMePh ₂)	– 3324
W(I)	
[(W(CO) ₃ (Cp)) ₂]	– 4040
W(II)	
[W(CO) ₃ (Cp)Cl]	– 2406
[W(CO) ₃ (Cp)Br]	– 2584
[W(CO) ₃ (Cp)I]	– 2996
[W(CO) ₃ (Cp)Me]	– 3549
[W(CO) ₃ (Cp)H]	– 4017
W(IV)	
[W(Cp) ₂ H ₂]	– 4671
W(VI)	
WF ₆	– 1120
[W ₁₀ O ₂₂] ^{4–}	– 43
[WO ₄] ^{2–}	0
[W ₆ O ₁₉] ^{2–}	+ 59
[WCl ₆]	+ 2181

Cp = η^5 -cyclopentadienyl.

excitation energies, which must therefore be outweighed by the effects of metal–ligand covalency on r and the coefficients C . For the W(VI) complexes WF_6 and WCl_6 , however, the order expected from excitation energies is observed.

One area where ^{183}W NMR has made a major contribution is in the study of iso- and heteropolytungstate ions. Since the tungsten atoms are usually in highly distorted octahedral environments, the relaxation times are short enough to allow convenient direct observation. The sensitivity of δ_w to the tungsten environment, and the observation of W–O–W coupling patterns, facilitate structural assignments. Paramagnetic heteropolytungstate ions have been included in these studies.

Where similar series of tungsten and molybdenum compounds have been studied by ^{183}W and ^{95}Mo NMR, respectively, there are close parallels between the two series. ^{95}Mo , ($I = \frac{5}{2}$) is quadrupolar, and lines are relatively broad in unsymmetrical environments. Magic-angle spinning (MAS) solid-state ^{183}W NMR spectra may be obtained, but long spectrometer times are usually required because of long spin–lattice relaxation times.

Platinum, ^{195}Pt

The only platinum nucleus with magnetic properties is ^{195}Pt , $I = \frac{1}{2}$, (33.7% abundance). The resonance frequency in a magnetic field of 2.35 T is approximately 21.4 MHz. ‘Satellite’ peaks from coupling with ^{195}Pt were observed in 1H and ^{31}P NMR spectra in the 1960s, and much of the early work on ^{193}Pt detection used INDOR methods. Direct one-dimensional observation of ^{195}Pt NMR spectra is now routine. Because ^{195}Pt relaxation times are short for most compounds, there need be only a very short delay between pulses, allowing rapid accumulation. Two-dimensional inverse detection methods are also being increasingly used. A comprehensive review of ^{195}Pt NMR spectroscopy, including both theoretical and practical aspects, has appeared, and is listed in the Further Reading list.

The most commonly used reference for ^{195}Pt NMR is an aqueous solution of $Na_2[PtCl_6]$. As a number of authors have pointed out, there are some disadvantages in using this substance. At high magnetic fields, peaks due to different combinations of chlorine isotopes may be resolved, and the resonance frequency is significantly dependent on temperature. This leads to some uncertainty (up to ± 5 ppm) in reported chemical shifts, but this is not very significant in the context of the overall chemical shift range for platinum ($\sim 15\,000$ ppm). However, this reference does have the great advantage of convenience, and is therefore unlikely to be supplanted. Other suggestions have been $[Pt(CN)_6]^{2-}$ (-3863 ppm) and Ξ_{Pt} , a frequency of exactly 21.4 MHz in a magnetic

field in which the resonance frequency of tetramethylsilane (TMS) is exactly 100 MHz (-4533 ppm). An aqueous solution of $K_2[PtCl_4]$ ($\delta_{Pt} - 1624$ ppm) is sometimes used as a secondary reference. Of greater concern than the small uncertainty in the reference frequency is the possibility, with a very wide chemical shift range for ^{195}Pt , of observing ‘folded’ peaks. If peaks are not carefully ‘checked for folding’, reported shifts may be in error by hundreds of ppm!

Chemical shifts for some representative platinum compounds are given in Table 2. The order of ligands in their effect on δ_{Pt} is similar to that on other well-studied transition metals (e.g. ^{59}Co , ^{103}Rh). In particular, ligands with heavy donor atoms tend to cause increased shielding of the metal nucleus so that, for example, the shielding increases from Cl^- to Br^- to I^- . As discussed above for W(II) compounds, this may be understood in terms of the heavier donor atoms having a greater effect on r and C in eqn [1].

Table 2 ^{195}Pt chemical shifts for some representative compounds

Compound	δ_{Pt}
Pt(0)	
$[Pt(PPh_3)_3]$	-4583
$[Pt(1,5\text{-cyclooctadiene})_2]$	-4636
$[Pt(PMe_2Ph)_4]$	-4728
$[Pt(PCy_3)_2]$	-6501
Pt(I) (Pt–Pt bond)	
$[(PtCl_2(CO))_2]^{2-}$	-4162
Pt(II)	
$[Pt(H_2O)_4]^{2+}$	$+31$
$[(Pt(NH_3)_2(\mu-OH))_2]^{2-}$	-1153
$[PtCl_3(H_2O)]^-$	-1180
<i>trans</i> - $[Pt(NH_3)_2(H_2O)_2]^{2+}$	-1374
$[(Pt(NH_3)_2(\mu-OH))_3]^{3-}$	-1505
<i>cis</i> - $[Pt(NH_3)_2(H_2O)_2]^{2+}$	-1584
$[PtCl_4]^{2-}$	-1620
$[PtCl_3(NMe_3)]^-$	-1715
$[Pt(en)(H_2O)_2]^{2+}$	-1914
<i>trans</i> - $[PtCl_2(NH_3)_2]$ (indmf)	-2101
<i>cis</i> - $[PtCl_2(NH_3)_2]$ (indmf)	-2104
$[Pt(NO_2)_4]^{2-}$	-2166
$[Pt(NH_3)_4]^{2+}$	-2580
$[PtBr_4]^{2-}$	-2690
$[PtCl_3(SMe_2)]^-$	-2757
$[PtCl_3(PMe_3)]^-$	-3500
$[Pt(CN)_4]^{2-}$	-4746
Pt(III) (Pt–Pt bond)	
$[(H_2O)Pt(\mu-SO_4)_2]^{2-}$	$+1753$
$[ClPt(\mu-P(O)_2O(O)_2P)_2]^{4-}$	-4236
Pt(IV)	
$[PtF_6]^{2-}$	$+7314$
$[Pt(OH)_6]^{2-}$	$+3277$
$[PtCl_6]^{2-}$	0
<i>fac</i> - $[PtMe_3(H_2O)_3]^+$	-1794
$[PtBr_6]^{2-}$	-1860
$[Pt(CN)_6]^{2-}$	-3866

While δ_{Pt} depends primarily on the donor atom set, the nature of the whole ligand does have an important effect (compare, for example, $[\text{Pt}(\text{NH}_3)_4]^{2+}$ and $[\text{Pt}(\text{NO}_2)_4]^{2-}$). Geometric isomers will also have different shifts, which are greatest when the different ligands bound to the metal are very different in their *trans* influence (compare the *cis* and *trans* pairs $[\text{PtCl}_2(\text{NH}_3)_2]$ and $[\text{Pt}(\text{NH}_3)_2(\text{H}_2\text{O})_2]^{2+}$). There are also ‘ring-size’ effects, evident in the difference between the shifts for $[\{\text{Pt}(\text{NH}_3)_2(\mu\text{-OH})\}_n]^{n+}$ with $n=2$ (four-membered ring) and $n=3$ (six-membered ring), and for *cis*- $[\text{Pt}(\text{NH}_3)_2(\text{H}_2\text{O})_2]^{2+}$ and $[\text{Pt}(\text{en})(\text{H}_2\text{O})_2]^{2+}$ (five-membered chelate ring).

Chemical-shift anisotropy relaxation is important for platinum complexes, especially for square planar complexes, and at high magnetic field strengths. It is also enhanced when there is significant hydrogen-bonding between the solvent and solute (as with diammineplatinum compounds in water), and when platinum is coordinated to bulky ligands (both of which will decrease the rate of tumbling in solution). Fast CSA relaxation leads to broadening of peaks and loss of resolved splittings from couplings. It can also effectively decouple platinum from another nucleus which is being observed. Coupling constants involving ^{195}Pt [e.g. $^1J(\text{Pt}-^{31}\text{P})$, $^1J(\text{Pt}-^{15}\text{N})$, $^1J(\text{Pt}-^1\text{H})$, $^1J(\text{Pt}-^{13}\text{C})$, $^2J(\text{Pt}-\text{CH}_3)$, $^2J(\text{Pt}-\text{CF}_3)$] can provide useful structural information (e.g. through the *trans* influence of the *trans* ligand on these couplings) which may therefore be lost at high magnetic fields. In compounds containing platinum–platinum bonds, the magnitude of $J(\text{Pt}-\text{Pt})$ does not appear to be related simply to bond length or bond strength, although $J(\text{Pt}-\text{Pt})$ is affected in the same way as other coupling constants by the *trans* influence of the ligands *trans* to the metal–metal bond.

When platinum is bound by ligands with donor atoms having quadrupolar nuclei (e.g. ^{14}N , ^{75}As), NMR peaks are frequently broad, because the rate of quadrupole-induced relaxation is such that ^{195}Pt is only partially decoupled from the quadrupolar nucleus.

Solid state ^{195}Pt NMR spectra, including CP-MAS spectra, have been obtained. Much higher spinning rates are required for platinum(II) compounds than for most platinum(IV) complexes, because of their much greater shielding anisotropy.

Mercury, ^{199}Hg

Mercury has two isotopes with $I > 0$, ^{199}Hg ($I = \frac{1}{2}$; 16.8% abundance) and ^{201}Hg ($I = \frac{3}{2}$; 13.2% abundance). Because of the large quadrupole moment of ^{201}Hg , this nucleus is not readily observed, and only ^{199}Hg is of significance for NMR spectroscopy. Its resonance frequency in a magnetic field with strength 2.35 T

is 17.9 MHz. There is a general agreement on the use of neat dimethylmercury as reference, despite the high toxicity of this substance. An aqueous solution of $\text{Hg}(\text{ClO}_4)_2$ (–2253 relative to Me_2Hg) has been suggested as an alternative but its shift is dependent on concentration and temperature.

Common coordination behaviour for $\text{Hg}(\text{II})$ involves strong linear coordination by two ligands, often with additional weaker interactions from solvent molecules, counter-ions, etc. In some cases, (e.g. halides X^-) higher coordination numbers are possible (e.g. tetrahedral $[\text{HgX}_4]^{2-}$). There is considerable ligand lability so that averaged signals are often observed. There is therefore often some uncertainty about the precise nature of the species being observed.

Chemical shift anisotropies are also large (except for highly symmetrical $[\text{HgX}_4]^{2-}$), leading to efficient relaxation, and some line broadening at high magnetic fields. Two-dimensional NMR spectra may be readily obtained.

Some ^{199}Hg chemical shift data are given in Table 3 for some representative compounds whose structures appear to be fairly well defined in solution. As with typical transition metals, such as ^{195}Pt and ^{113}Cd , the nuclear shielding increases in halide complexes as the halide ion becomes heavier (‘normal halide dependence’).

Coupling constants between ^{199}Hg and other nuclei [e.g. ^{13}C , ^{31}P and ^1H (2J , 3J)] have been extensively studied. In a series of complexes (e.g. CH_3HgX) the coupling constants [$^2J(\text{Hg}-\text{CH}_3)$ in this instance] may be used to establish a *trans* influence series which is similar to that obtained from coupling constants involving ^{195}Pt .

Other Elements, La–Hg

Lanthanum

Nuclei with $I > 0$ are ^{139}La , ($I = \frac{7}{2}$; 99.91% abundance) and ^{138}La ($I = 5$; 0.09% abundance). Because of its low natural abundance, ^{138}La is of no practical importance for

Table 3 ^{199}Hg shifts for some representative compounds

Compound	δ_{Hg} (ppm)
Hg(I)	
$[\text{Hg}_2]^{2+}(\text{ClO}_4)_2/\text{H}_2\text{O}(\text{satd.})$	– 1614
Hg(II)	
Me_2Hg	0
MeHgCl	– 813
MeHgBr	– 915
$[\text{MeHg}(\text{NH}_3)]\text{BF}_4$	– 943
MeHgI	– 1097
$[\text{MeHg}(\text{OH}_2)]^+$	– 1150
$[\text{HgCl}_4]^{2-}$	– 1200
$[\text{HgBr}_4]^{2-}$	– 1810
$[\text{Hg}(\text{H}_2\text{O})_6](\text{ClO}_4)_2$	– 2253
$[\text{HgI}_4]^{2-}$	– 3510

NMR spectroscopy. The common oxidation state, La(III), is diamagnetic but coordination complexes are usually labile, and quadrupole-induced relaxation causes broad line widths, except when the environment is highly symmetric, as in $[\text{LaX}_6]^{3-}$ complexes, which are presumably octahedral. Both the chemical shift and line width can provide information about the average environment of the La^{3+} ion. As expected for a d^0 ion, the metal nucleus is less shielded in $[\text{LaBr}_6]^{3-}$ (+1090 ppm from aqueous La^{3+}) than in $[\text{LaCl}_6]^{3-}$ (+851 ppm).

Other Lanthanides

Diamagnetic oxidation states tend to be unstable in aqueous solution, except for Yb(II) and Lu(III). Since ^{171}Yb (14.3% abundance) has $I = \frac{1}{2}$, there have been some solution studies on Yb(II) complexes. ^{169}Tm (100% abundance) also has $I = \frac{1}{2}$, but diamagnetic compounds are not stable in solution. ^{175}Lu ($I = \frac{7}{2}$; 97.4% abundance) has a large quadrupole moment, which limits its use. Solid state spectra have been obtained on paramagnetic compounds using nuclei with relatively low quadrupole moments: ^{141}Pr ($I = \frac{5}{2}$; 100% abundance), ^{151}Eu ($I = \frac{5}{2}$; 47.8% abundance), ^{159}Tb ($I = \frac{3}{2}$; 100% abundance), ^{165}Ho ($I = \frac{7}{2}$; 100% abundance) and with ^{169}Tm ($I = \frac{1}{2}$; 100% abundance).

Hafnium

^{171}Hf , ($I = \frac{7}{2}$; 18.5% abundance) and ^{179}Hf , ($I = \frac{9}{2}$; 13.8% abundance) have large quadrupole moments, causing severe line broadening.

Tantalum

^{181}Ta ($I = \frac{7}{2}$; 99.99% abundance) also possesses a large quadrupole moment so that, even in octahedral species such as $[\text{TaCl}_6]^-$, lines are broad.

Rhenium

^{185}Re , ($I = \frac{5}{2}$; 37.1% abundance) and ^{187}Re ($I = \frac{5}{2}$; 62.9% abundance) also have large quadrupole moments so that the line widths are large even for the symmetric species $[\text{ReO}_4]^-$.

Osmium

^{187}Os has $I = \frac{1}{2}$, but its low natural abundance (1.64%) and its very low receptivity and often long T_1 relaxation times make it difficult to observe. ^{189}Os ($I = \frac{3}{2}$; 16.1% abundance) has a large quadrupole moment, leading to very broad lines, except in highly symmetric environments. The chemical shift reference for ^{187}Os NMR is often OsO_4 . In some cases, ^{187}Os spectra may be obtained by indirect

detection, such as the HSQC experiment, using more sensitive nuclei such as ^1H or ^{31}P . Coupling constants between ^{187}Os and other nuclei (e.g. ^{31}P , ^{13}C) may be easily observed, and provide structural information.

Iridium

^{191}Ir ($I = \frac{3}{2}$; 37.3% abundance) and ^{193}Ir , ($I = \frac{3}{2}$; 62.7% abundance) have large quadrupole moments, low receptivity and low resonance frequencies, which make observation difficult.

Gold

^{197}Au ($I = \frac{3}{2}$; 100% abundance) has a large quadrupole moment. With the preferred linear $[\text{Au(I)}]$ and square planar $[\text{Au(III)}]$ geometries, quadrupole-induced relaxation is very fast, and signals have not been observed in solution.

NMR Spectroscopic Properties and Techniques for ^{17}O , ^{33}S , ^{77}Se and $^{123,125}\text{Te}$

Nuclear Properties

Both ^{17}O and ^{33}S are quadrupolar nuclei with very low natural abundance (Table 1). The NMR active isotopes of selenium and tellurium are spin $\frac{1}{2}$ nuclei. The receptivity of ^{77}Se is about three times larger than that of ^{13}C . The element tellurium has two active isotopes, $^{123,125}\text{Te}$. ^{125}Te has been used in the majority of tellurium NMR investigations owing its significantly better receptivity.

Experimental Techniques

The stringent requirements in ^{17}O and ^{33}S NMR studies of compounds at natural abundance are the high concentrations and extensive signal averaging needed. Recording of spectra can be greatly facilitated by the use of enriched samples. Synthesis with oxygen isotopes involves rather straightforward organic reactions. The quadrupolar moments of ^{17}O and ^{33}S result in very effective relaxation and, thus, extensive line broadening with T_1 and T_2 relaxation times often in the range below 1 ms. A possible

way to attenuate extensive line-broadening effects is to use higher temperatures and/or solvents of low viscosity. Observation of very broad (> 1 kHz) resonances, however, is a potential problem due to baseline distortions. The most severe origin of baseline artifacts is the transient response of the NMR probe, often referred to as ‘acoustic ringing’, caused by the generation of ultrasonic waves from the action of the RF pulse. Several methods have been proposed to overcome this problem, with particular emphasis on multipulse sequences.

The longitudinal relaxation of ^{77}Se and ^{125}Te at high fields is governed by the spin–rotation (SR) mechanism with typical T_1 values in the range of 1–30 s. In the solid state the relaxation times are very long; consequently the use of MAS NMR with cross polarization from ^1H is necessary. The ^{77}Se and ^{125}Te shieldings indicate a strong temperature dependence (several ppm/K), and so extreme care is necessary to maintain constant temperature, particularly when broadband decoupling is employed.

As is common with many heteronuclei, a variety of reference compounds and referencing procedures (both internal and external) have been suggested. The most commonly used standards ($\delta = 0$, as external reference) are H_2O (a temperature dependence of the ^{17}O shielding has been reported) or 1,4-dioxane at 30°C for ^{17}O ; $(\text{NH}_4)_2\text{SO}_4$ or Cs_2SO_4 in water for ^{33}S ; Me_2Se in CDCl_3 for ^{77}Se and Me_2Te in CDCl_3 for ^{125}Te .

^{17}O NMR Parameters and Applications

^{17}O Shieldings

The total range of ^{17}O shieldings of diamagnetic compounds is about 2600 ppm (Figure 1). For compounds

Table 1 Nuclear properties of ^{17}O , ^{33}S , ^{77}Se , ^{123}Te and ^{125}Te

Isotope	Spin	Natural abundance (%)	NMR frequency ^a (MHz)	Receptivity

^cProduct of relative receptivity and natural abundance.

Figure 1 ^{17}O chemical shift ranges of selected diamagnetic oxygen functional groups.

containing oxygen bonded only to carbon and/or hydrogen there is a clear correlation between C–O π bond order and high frequency shift. This type of correlation arises from the multiple bond term in the Karplus–Pople equation. Bridging oxygens indicate a strong deshielding for π -accepting acyl substituents which introduce π character into the C–O bond of the bridging oxygen.

In nitrogen compounds, chemical shift values are also determined largely by π bonding effects. Bridging oxygen resonances are observed at higher frequencies in nitrites ($\text{R}-\text{O}-\text{N}=\text{O}$), where π bonding is appreciable. A lesser but nonetheless significant effect is observed for bridging oxygens in nitrates ($\text{R}-\text{O}-\text{NO}_2$). The most striking feature of the ^{17}O shifts observed for P–O bonds is the small chemical shift range (20–260 ppm) which cannot be related to P–O bond order in a straightforward fashion. However, ^{17}O resonances for non-equivalent oxygens in phosphates and polyphosphates could be resolved and could be utilized in stereochemical and binding site studies. For S–O bonding, similar trends to those of P–O bonds were observed. Modification of π -bond order in a $\text{X}=\text{O}$ group due to substituents on X results in a

decrease (or increase) in the net charge on X as the charge on O increases (or decreases). The chemical shift variations experienced by the nuclei X and O are then opposite and roughly proportional to the ratio $\langle r^{-3} \rangle 2P_{\text{X}} / \langle r^{-3} \rangle 2P_{\text{O}}$.

For a series of oxyanions and a series of $\text{C}=\text{O}$ and $\text{N}=\text{O}$ compounds a linear correlation between $\delta(^{17}\text{O})$ and the inverse of the lowest energy $n \rightarrow \pi^*$ transition was found. A linear correlation exists between acetone chemical shifts and the maximum of the $n \rightarrow \pi^*$ transition for acetone–water solutions or for acetone in different solvents. Similar trends have also been observed in a variety of substituted acetophenones; however, it was suggested that such trends may be fortuitous. In a series of aliphatic ethers a correlation between $\delta(^{17}\text{O})$ and the first ionization potential was suggested.

Compounds that contain oxygen–oxygen bonds and oxygen–fluorine bonds display large high frequency shifts. The ability, therefore, of ^{17}O NMR to unambiguously distinguish between non-equivalent oxygens has found application in several structural and mechanistic studies. Many stereochemical studies have dealt with polynuclear, anionic oxo complexes (polyoxoanions) of the early

transition elements in their highest oxidation states. Despite their structural complexity, these polyoxoanions often yield well-resolved ^{17}O NMR spectra since large shielding ranges are observed and samples may be studied at elevated temperatures in nonviscous solvents. Furthermore, ^{17}O enrichment can easily be obtained.

Indirect Spin Coupling Constants

Because of the breadth of ^{17}O resonances, only relatively large coupling constants can be measured and hence the majority of those recorded refer to couplings from directly bonded nuclei. $^1J(\text{O,H})$ in water and in alcohols has a value close to 80 Hz. The $^1J(\text{P,O})$ couplings involving $\text{P}=\text{O}$ groups cover a fairly wide range (145–210 Hz) and for a series of compounds of type OPX_3 ($\text{X}=\text{F}$, O in OMe , N in NMe_2 and C in Me) there is a consistent drop in coupling with decreasing electronegativity of X . The oxygens in $\text{P}-\text{OMe}$ groups within phosphates give rise to a consistently smaller coupling constant, compared with $\text{P}=\text{O}$, of between 90 and 100 Hz. The reduced coupling constants decrease with increasing atomic number of the central atoms along the isoelectronic sequence VO_4^{3-} , CrO_4^{2-} and MnO_4^- . An application of ^{17}O spin-spin couplings has been made to investigate H_3O^+ species.

Nuclear Quadrupole Coupling Constants (χ)

Experimental χ values cover a range from -8 to 17MHz . The experimental χ values for a series of compounds in the solid state with $\text{C}=\text{O}$, $-\text{O}-$, PO , NO , and SO bonds show the following trends:

Strong hydrogen bonding reduces the χ values by up to 2.6MHz . The χ values of the terminal CO groups in metallocarbonyls were found to be between 1 and 3MHz although values below 0.1MHz have also been observed. It was suggested that increased $d\pi\text{-}p\pi$ back bonding from the metal will increase electron density perpendicular to the $\text{C}-\text{O}$ axis and so reduce χ values.

Dynamic and Kinetic Studies

Numerous dynamic and kinetic studies have been performed using ^{17}O NMR. Line shape analysis is not straightforward because the line width itself is temperature dependent. Nevertheless, it has been shown that dynamic ^{17}O NMR is a convenient alternative to ^{13}C

NMR with, for example, methyl carbonyl compounds. A substantial number of publications have been concerned primarily with studies of the hydration (solvation) of ions in solution and the determination of rates and activation parameters for ligand substitution. There is an extensive literature of ^{17}O NMR spectroscopy used for the study of hyperfine interactions between the unpaired electrons in paramagnetic molecules and ions and the ^{17}O nucleus. The magnitudes and temperature dependences of line widths (or relaxation time measurements) of the 'bound' and 'free' resonances, and the chemical shift separations between those resonances, can in principle be used to derive information about the hyperfine splitting constant, the rate of the solvent interchange process and the solvation number. However, because the shifted resonance of the solvated water molecules is often very broad, it is usually not possible to derive the hydration number of the paramagnetic cation from straightforward area measurements. In these cases, the hydration numbers may be obtained by the use of theory developed by Swift and Connick.

Torsion Angle and Hydrogen Bonding Effects

^{17}O NMR spectroscopy is a powerful method for the detection of steric effects in molecules in which steric interactions are characterized by rotation of functional groups around single bonds to relieve van der Waals interactions or on rigid systems in which steric interactions are partially accommodated by bond angle and bond length distortions. Applications include aromatic and heteroaromatic nitro compounds, aryl ketones, aldehydes, 1,2-diketones, aromatic carboxylic acids, esters and amides.

^{17}O NMR appears to be especially promising for use in hydrogen bonding interaction studies because of the large chemical shift range of the oxygen nucleus. The dominance of intramolecular hydrogen bonding effects over substituent effects was clearly demonstrated in acetophenones, benzaldehydes and hydroxynaphthoquinones. Detailed studies of the influence of intermolecular solute-solvent hydrogen bonding in amides and peptides demonstrate that both long-range dipole-dipole interactions and hydrogen bonds at the amide oxygen induce significant and specific shielding of the ^{17}O nucleus.

Water Orientation in Lyotropic Phases and Bilayers - Hydration of Proteins and DNA

^{17}O NMR studies have several advantages compared with ^1H and ^2D NMR for investigating water orientation in lyotropic phases and bilayers and the hydration of proteins and DNA since the relaxation effect is large and the intramolecular origin of the electric field gradient makes the quadrupolar interaction virtually independent of the molecular environment. Recently, it has been suggested

that the relaxation dispersion in aqueous protein and DNA solutions in the MHz frequency range is not due to a long-lived hydration layer at the biomolecular surface, but to a small number of crystallographically well-defined water molecules.

The Solid State

Under conditions of magic-angle spinning (MAS) the powder band shape of the ($\frac{1}{2}$, $-\frac{1}{2}$) transition of quadrupolar nuclei with non-integral spin does not depend on first-order quadrupolar interactions but only upon second-order quadrupolar effects, giving the possibility of obtaining meaningful NMR spectra. In this case operation at very high magnetic fields will generally be most advantageous since the maximum second-order quadrupolar line width of the ($\frac{1}{2}$, $-\frac{1}{2}$) transition decreases linearly with the magnetic field. Typical results are those obtained for a range of oxides, oxyanions and high-temperature oxide superconductors.

^{33}S NMR Parameters and Applications

^{33}S Shieldings

^{33}S shieldings cover a range of about 1000 ppm. Four regions (with several exceptions) can be identified: (a) singly bonded sulfur, (b) multiple bonded sulfur, (c) sulfur in delocalized π systems and (d) $\text{S}=\text{O}$ bonds. The sulfur nucleus in thiols and thioethers is strongly shielded ($\delta = -300$ to -510 ppm). Oxidation to sulfoxides results in 300–400 ppm deshielding ($\delta = +40$ to -100 ppm). Further oxidation to sulfones does not significantly change $\delta(^{33}\text{S})$ values ($\delta = +40$ to -30 ppm). Sulfur in three- and four-membered ring compounds ([1]–[3]) is more shielded than in the corresponding acyclic and cyclic analogues of larger ring sizes (similar trends have been observed for ^1H , ^{13}C and ^{17}O nuclei).

The resonance range of sulfones is about 60 ppm and it has been used to follow the analysis of sulfur-containing oils after oxidation of the sulfur species. The values of $\delta(^{33}\text{S})$ in sulfonamides are quite similar to those of sulfones. Sulfoximines $[\text{R}-(\text{O}=\text{S})(=\text{NR}'')-\text{R}']$ resonate at lower frequencies than the corresponding sulfones $[\text{R}-\text{S}(=\text{O})_2-\text{R}']$, which may be attributed to the lower electronegativity of the doubly bonded NR group in the sulfoximine replacing the oxygen in sulfones. The opposite is seen when sulfimines $[\text{R}-\text{S}(=\text{NR}'')-\text{R}']$ are

compared with the corresponding sulfoxides $[\text{R}-\text{S}(=\text{O})-\text{R}']$.

Sulfuric acid and sulfates resonate around $\delta = 0$. Significant deshieldings have been observed when oxygen is replaced gradually by sulfur in thiomolybdate anions. Thiotungstates show a similar trend. Sulfides cover a wide range, over 600 ppm (e.g. -680 and -42 ppm for Li_2S and BaS , respectively). This can be attributed to different bond characters (ionicities) in the crystal.

Substituent effects in diorganyl sulfones, 3- and *trans*-3,4-substituted thiolane 1,1-dioxides and 4-substituted 2-thiolene 1,1-dioxides have been investigated and correlations with ^{13}C and ^{17}O in analogous compounds as well as with Taft (Hammett) electronic parameters have been reported. Stereochemical effects on ^{33}S shielding have been studied such as the stereomeric sulfones [4] and [5].

^{33}S Coupling Constants

There is a limited number of ^{33}S coupling constants in the literature due to severely broadened signals. $^2J(^{33}\text{S}-^1\text{H})$ coupling constants of 3 and 4.5 Hz were measured for Me_2SO_2 and sulfolane and a $^3J(^{33}\text{S}-^1\text{H})$ coupling constant of 6 Hz for 2,5-dihydrothiophene 1,1-dioxide. One-bond $^{33}\text{S}-^{19}\text{F}$ coupling of ~ 252 Hz has been found for SF_6 .

^{33}S Relaxation Times

The line widths of ^{33}S cover a range of 10 to 300 Hz for $[\text{MoS}_n\text{O}_{4-n}]^{2-}$ and $[\text{WS}_n\text{O}_{4-n}]^{2-}$ ($n = 1-4$), > 4 kHz for sulfoxides and > 9 kHz for sulfonium salts. The narrow ^{33}S signal in solid ZnS can be attributed to cubic symmetry and magnetic dilution of this compound.

^{77}Se NMR Parameters and Their Applications

^{77}Se Shieldings

The total range of ^{77}Se shieldings is about 3300 ppm. Figure 2 illustrates the resonance ranges of various selenium functional groups. Electropositive substituents such as H_3Si and H_3Ge attached to selenium result in very strong shielding ($\delta = -666$ and -612 ppm, respectively). Selenide ions are even more shielded, e.g. K_2Se ($\delta = -670$ ppm) and $\text{H}_3\text{Si}-\text{Se}^-\text{Li}^+$ ($\delta = -736$ ppm). Increasing electronegativity of substituents directly attached to selenium in $\text{R}-\text{Se}-\text{X}$ (R-organyl) results in

Figure 2 (a) ^{77}Se chemical shift ranges of selected selenium functionalities (excluding metal complexes). (b) ^{77}Se chemical shift ranges of compounds containing C=Se groups (excluding metal complexes). Reproduced by permission of John Wiley and Sons from Dudgeon H (1996) Sulfur, selenium and tellurium NMR. In: Grant DM and Harris RK (eds.) *Encyclopedia of Nuclear Magnetic Resonance*, pp. 4623–4635. Copyright 1996. John Wiley & Sons.

deshielding. In selenium halides (SeX_2), strong shielding is observed with decreasing electronegativity of X in the series $\text{X} = \text{Cl}$ ($\delta = 1758$ ppm), Br ($\delta = 1474$ ppm) and I ($\delta = 814$ ppm). Deshielding, but with an opposite trend to the halogen effect, is observed for the oxygenated species: SeOF_2 ($\delta = 1378$ ppm), SeOCl_2 ($\delta = 1479$ ppm) and SeOBr_2 ($\delta = 1559$ ppm).

Alkyl substituents in dialkyl and arylalkyl selenides have a significant deshielding effect on $\delta(^{77}\text{Se})$, with β -effects being larger than α -effects. Analogous trends have been observed for phenylselenenylalkanes (PhSe-R), alkylselenols (RSeH), alkylselenolates (RSe-Na^+) and in dialkyl diselenides (RSeSeR). The γ -effects are substantially shielding. The large magnitudes of α -, β - and γ -effects have been discussed in terms of intramolecular polarizability effects. The $\delta(^{77}\text{Se})$ of selenoanisoles (Ph-Se-Me) substituted at the aromatic ring have been expressed in terms of dual substituent parameters (DSP).

Oxidation of Se(II) and Se(IV) generally results in significant deshielding: Me_2Se ($\delta = 0$ ppm), Me_2SeBr_2 ($\delta = 389$ ppm) and Me_2SeCl_2 ($\delta = 448$ ppm). The magnitudes of substituent effects of alkyl groups are approximately four times smaller in the selenoxides than in the corresponding selenides. Halogenated species show the opposite tendency.

Se(VI) species are shielded compared with the structurally related Se(IV) analogues: H_2SeO_4 ($\delta = 1001$ ppm) and H_2SeO_3 ($\delta = 1300$ ppm). The $\delta(^{77}\text{Se})$ of hypervalent tetraarylselenium compounds are not significantly different compared with those of divalent diaryl selenides.

The C=Se functional group shows shieldings which cover the whole of the known range of $\delta(^{77}\text{Se})$: selenoaldehyde ($\delta = 2398$ ppm) and O=C=Se ($\delta = -447$ ppm). Shieldings strongly depend on the nature of the atoms and substituents attached to the carbon of the C=Se group. Furthermore, correlations with $n \rightarrow \pi^*$

transitions and $\delta(^{17}\text{O})$ in C=O analogues have been found.

Cyclic compounds with selenium in the ring(s) have been comprehensively investigated. Annulation of conjugated ring systems to selenophene causes considerable shieldings. Replacement of carbon by an electronegative element such as nitrogen atom results in a deshielding by up to 900 ppm. Even minor strain effects within the heterocycle can cause significant shielding. As expected, positively charged unsaturated ring systems cause extreme deshielding effects.

P=Se bonds indicate negative $\delta(^{77}\text{Se})$ values which was attributed to the dipolar mesomeric form II: $-\text{P=Se}$ (I) $\leftrightarrow$ $-\text{P}^+-\text{Se}^-$ (II). Shieldings depend strongly on the nature of the substituent at phosphorus and the branching of carbon substituents.

There is a large number of $\delta(^{77}\text{Se})$ of selenium-metal compounds which, according to Dudgeon, can be classified into three types: (a) selenium with covalent bonds to main group metals. Deshielding is usually observed compared with the corresponding selenide anions. (b) Selenium σ -, π -, μ - or η -coordinated to transition metal atoms. The $\delta(^{77}\text{Se})$ of these complexes cover the whole

shift range. In most cases deshielding is observed compared with the free selenium-containing ligand. Strong shieldings have been observed in the case of the η^4 -cobalt complexes compared with the free heterocycles. (c) Selenium ligands with other atoms (usually phosphorus or nitrogen) directly coordinated to the metal atom. The $\delta(^{77}\text{Se})$ of this type of metal complexes do not differ significantly from those of the free ligands.

Variable temperature NMR has been utilized in the conformational analysis of selenium-containing compounds such as the ring inversion process of phenylselenenylcyclohexane, 2,11-diselena[3.3] metacyclopentane, [3.3]diselena- and [4.4]tetraselenacyclopentanes and 1,4,5,7-tetrahydro-3*H*-2,6-benzodiselenines.

^{77}Se NMR has been utilized as a tool for chiral recognition which occurs across several bonds such as in the derivatizing agent (4*S*,5*S*)-(–)-4-methyl-5-phenyl-oxazolidine-2-selone.

CP MAS ^{77}Se NMR in the solid has been utilized to investigate conformational properties in cyclic compounds and comparison with X-ray structures. $\delta(^{77}\text{Se})$ were found to be strongly dependent on the crystallographic non-equivalences in the unit cell.

^{77}Se Coupling Constants

^{77}Se coupling constants are abundant in the literature since they can be investigated in a straightforward way from the spectra of the coupling partner such as ^1H , ^{13}C and ^{31}P nuclei. The J values have been reviewed extensively, so in this article only a synopsis will be given.

$^nJ(^{77}\text{Se}, ^1\text{H})$

One-bond coupling constants are, presumably, positive with values between 65.4 Hz (H_2Se) and 5.3 Hz for $\text{Cp-W}(\text{CO}_3)\text{SeH}$. Geminal couplings are mostly positive and vary between 4 and 16 Hz for hydrogen atoms in aliphatic fragments, but can increase to 50 Hz if the fragment has further geminal heteroatoms or if it is in a heteroatom ring. Two- and three-bond (vicinal) coupling constants show some stereochemical dependence.

$^nJ(^{77}\text{Se}, \text{and other nuclei})$

One-bond couplings $^1J(^{77}\text{Se}, ^{13}\text{C})$ are negative and strongly depend on the hybridization of the carbon atom. Typical values are -45 to -100 Hz for $\text{Csp}^3\text{-Se}$. Geminal couplings (<15 Hz for aliphatic carbons) and

vicinal couplings (3–12 Hz) are very little investigated and it is not clear whether a Karplus-type dependence exists.

There are very few reports of $^{77}\text{Se}\text{-}^{15}\text{N}$ couplings (60.1 Hz for $\text{CF}_3\text{Se-NH}_2$). One-bond $^{77}\text{Se}\text{-}^{19}\text{F}$ coupling constants considerably exceed 1000 Hz and strongly depend on the stereochemical position of the fluorine atoms (for SeF_4 the coupling to the axial fluorine atom is 284 Hz and that to the equatorial one 1206 Hz). Geminal couplings can be substantial (~ 120 Hz in fluorinated 1,3-diselenetanes) and four-bond coupling constants of ~ 12 Hz have been observed.

Few data of one bond $^{77}\text{Se}\text{-}^{29}\text{Si}$ have been published and are generally in the region of 110–49 Hz. One-bond $^{77}\text{Se}\text{-}^{31}\text{P}$ couplings are negative and show a strong dependence on both the bond order between phosphorus and selenium (-800 to -1200 Hz for P=Se double bonds and -200 to -620 Hz for single bonds) and the stereochemistry of the compounds investigated.

One-bond $^{77}\text{Se}\text{-}^{77}\text{Se}$ couplings have been observed in a number of diselenides ($+22$ to -67 Hz) and polyselenide anions with charged selenide atoms (250 ± 20 Hz). Two-bond couplings can have large values, particularly in cyclic sulfur-selenium compounds (95–114 Hz). Three-bond couplings (3–16 Hz) have been observed and four-bond couplings up to 16 Hz have been observed in sulfur-selenium cyclic compounds.

Couplings to metal nuclei

Typical one-bond couplings to metal nuclei are ^{119}Sn , 500–1700 Hz; ^{207}Pb , 780–150 Hz; ^{103}Rh , 20–44 Hz; ^{113}Cd , 126–195 Hz; ^{183}W , 109–14 Hz; ^{195}Pt , 630–74 Hz (a strong dependence on the nature of the substituents and the stereochemistry has been emphasized) and ^{199}Hg , -1270 to -751 Hz.

^{125}Te NMR Spectral Parameters and Their Applications

^{125}Te Shieldings

The total range of ^{125}Te shieldings is nearly 5000 ppm. The $\delta(^{125}\text{Te})$ of phosphine tellurides, R_3PTe , lie between

[9] $\delta = 175$ ppm

[10] $\delta = 209$ ppm

[11] $\delta = 989/983$ ppm

– 513 (R = Me) and – 1000 ppm (R = Pr^i) and have been interpreted in terms of the character of the P–Te bond.

The effects of replacing α -hydrogen atoms of dimethyl telluride and phenylmethyl tellurides or ditellurides are in close analogy to those in the corresponding selenides. The same holds for diorganytellurium dichlorides and difluorides. Similarly, $\delta(^{125}\text{Te})$ in *ortho*-substituted tellurophenetols can be correlated with analogous selenophenetols.

Telluroketones [6] indicate strong deshielding ($\delta = 2858$ ppm). If a heteroatom is attached to the tellurocarbonyl group, such as in [7], then a shielding is observed. The unusually high shielding ($\delta = -168$ ppm) for [8] has been interpreted in terms of the dipolar canonical form.

The (^{125}Te) of cyclic tellurium compounds indicate similar trends to those with the selenium analogues. Halogenation of the tellurium atom indicates strong deshielding. Furthermore, positively charged saturated and unsaturated ring systems cause extreme deshielding effects.

$\delta = 782$ ppm

$\delta = 727$ ppm

$\delta = 269$ ppm

X = Br, $\delta = 940$ ppm

$\delta = 257$ ppm

$\delta = 1304$ ppm

Variable temperature ^{125}Te NMR has been utilized to investigate ring inversion in phenyltellurenyl-substituted

cyclohexane derivatives. ^{125}Te NMR was shown to be an excellent tool for chiral recognition. Thus, the ^{125}Te chemical shifts of the stereoisomeric bicyclic compounds [9] and [10] differ by 34 ppm. Interestingly long-range effects, through several bonds, of the menthyl residue in [11] on tellurium shieldings have been observed.

Very few CP MAS ^{125}Te NMR studies in the solid have been reported; however, they clearly demonstrate the great sensitivity of the method in investigating even minor distortions from octahedral crystallographic symmetry.

^{125}Te Coupling Constants

^{125}Te coupling constants are less abundant in the literature than those involving ^{77}Se and are of the opposite sign due to the negative magnetogyric ratio of ^{125}Te . The ratio $J(^{125}\text{Te}, \text{X})/J(^{77}\text{Se}, \text{X})$ is 2–3 (in absolute value) and very probably reflects differences in the Fermi contact interaction. One-bond coupling constants $^1J(^{125}\text{Te}, ^1\text{H})$ are negative (– 59 Hz for H_2Te), geminal couplings in dialkyltellurides are ~ 20 Hz and – 90 Hz in tellurophene. Vicinal couplings are smaller (Et_2Te , – 22.7 Hz).

One-bond $^1J(^{125}\text{Te}, ^{13}\text{C})$ couplings show a strong dependence on the hybridization state of the carbon atom (Me_2Te , 162 Hz; $(\text{H}_2\text{C}=\text{CH})_2\text{Te}$, 285 Hz; $\text{Me}-\text{Te}-\text{C}\equiv\text{C}-\text{Bu}$, 531 Hz). One-bond $^1J(^{125}\text{Te}, ^{19}\text{F})$ values are very large (TeF_6 , 3688 Hz; TeF_7^- , 2876 Hz; Ph_2TeF_2 , 530 Hz). The $^1J(^{125}\text{Te}, ^{31}\text{P})$ couplings strongly depend on the bond order ($\text{R}_3\text{P}=\text{Te}$, 1548–1743 Hz; $(\text{Bu}^t)_2\text{P}-\text{Te}-\text{P}(\text{Bu}^t)_2$, 451 Hz).

$^1J(^{183}\text{W}, ^{125}\text{Te})$ and $^1J(^{195}\text{Pt}, ^{125}\text{Te})$ couplings have also been reported.

Symbols

J	scalar coupling constant
q	electric field gradient
Q	nuclear quadrupole moment
r	receptivity
T_1	spin–lattice relaxation time
T_2	spin–spin relaxation time
$W_{1/2}, \Delta\nu_{1/2}$	resonance line width [at half-height]
γ	magnetogyric ratio
δ_{iso}	isotropic chemical shift
η	molecular asymmetry parameter
σ	shielding
$\sigma(\text{dia})$	diamagnetic contribution to shielding
$\sigma(\text{para})$	paramagnetic contribution shielding
τ_c	molecular correlation time

All of the 3d series metals have at least one magnetic nucleus and hence are accessible to NMR measurements. With the exception of ^{57}Fe , the nuclear spins are $>\frac{1}{2}$, i.e. the nuclei possess an electric nuclear quadrupole moment Q (an ellipsoidal distribution of the nuclear charge) which induces rapid ‘quadrupolar’ relaxation. Only one of these nuclei, viz. ^{51}V , belongs to the low- Q category and thus provides favourably sharp resonance signals even in compounds of low symmetry. Some of the nuclei have excellent relative receptivities r (^{45}Sc , ^{51}V , ^{55}Mn , ^{59}Co), comparable to that of ^1H ; for others, like ^{57}Fe and ^{61}Ni , the very low r causes detection problems. When other spectroscopic methods for providing information on the metal and its coordination sphere are less meaningful, e.g. electron absorption spectroscopy in closed shell systems (d^0 : Sc^{III} , Ti^{IV} , V^{V} , Cr^{VI} ; d^{10} : Mn^{VII} , Mn^{III} , Co^{I} , Ni^0 , Cu^{I} , Zn^{II}), metal NMR can be a valuable tool. The large shielding variations accompanying even minor changes in the coordination spheres of the metal nuclei in closed and open shell (d^4 , d^6 , d^8) compounds make direct NMR (i.e. probing of the metal nucleus itself) the method of choice when elucidating structural features, including their relation to the electron distribution in and the reactivity of a complex compound. Metal NMR is now being applied for the characterization of biological materials (note that V, Mn, Fe, Co, Ni, Cu and Zn are ‘biometals’) and their model compounds, and for catalyst

systems based on the first transition series metals. Applications in organometallic and coordination chemistry and speciation in solution are other fields of interest, and the use of metal NMR parameters as a basis for establishing thermodynamic and kinetic parameters is an intriguing new development. Increasingly, static and nonstatic solid-state measurements are employed.

The main interest has been directed towards ^{51}V , ^{59}Co and ^{57}Fe (the latter nowadays commonly detected by indirect methods relying on scalar coupling to a sensitive nucleus); the large amount of data available on vanadium in all of its oxidation states has led to several data compilations (see Further Reading).

Properties of the Nuclei, Sample Preparation and Spectrum Measurements

Table 1 lists nuclear properties. The only spin- $\frac{1}{2}$ nucleus in the 3d series is ^{57}Fe with a rather low receptivity (4.2×10^{-3} relative to ^{13}C ; 7.4×10^{-7} relative to ^1H), requiring special detection measures. Where applicable, ^{57}Fe NMR parameters are obtained by indirect methods, e.g. via ^1H or ^{31}P NMR in organoiron or phosphine–iron compounds. The rest of the nuclei possess an electric nuclear quadrupole moment and are therefore subject to effective quadrupole relaxation, i.e. short T_1 ($\approx T_2$) relaxation times and broad resonance lines. Three criteria have to be fulfilled if these nuclei are to be employed as NMR probes in a conventional solution NMR experiment, viz. (i) a reasonable receptivity, (ii) a reasonably small quadrupole moment, and (iii) a short molecular correlation time (τ_c)/small molecular electric field gradient (q). Except for ^{51}V , all quadrupolar nuclei belong to the medium quadrupole category, where criterion (iii) restricts conventional measurements to small, nonbulky molecules that have relatively high symmetries. ^{51}V , with a rather low quadrupole moment of $-0.052 \times 10^{-28} \text{ m}^2$, is susceptible to NMR in almost every environment, although there are examples, such as vanadate–protein complexes, where special detection modes (centred on the quadrupolar central transition) have to be employed to cope with the long τ_c . As to criterion (i), ^{45}Sc , ^{51}V , ^{55}Mn , ^{59}Co (and ^{63}Cu) are suitable nuclei. Resolution problems originating from broad resonance lines are

Table 1 NMR properties of 3d transition metal nuclei^a

often balanced by a very pronounced sensitivity of shielding towards even minor variations in the molecular structure.

Measurements in solution (including liquid-crystal solutions) are carried out using medium field strength spectrometers equipped with a multinuclear probe head. Some of the nuclei (⁴⁵Sc, ⁵¹V, ⁵⁵Mn, ⁵⁹Co, ⁶³Cu) have measuring frequencies close to that of ¹³C and can usually be detected using a broad-band ¹³C probe head. For nuclei exhibiting very large shielding ranges (mainly V, Cr, Mn, Fe, Co), one has to take care that the signals appear in the correct window (i.e. are not folded). For the quadrupolar nuclei, it is advisable to set the pulse width to 60–90° and to apply a line broadening factor. Relaxation delays can usually be avoided. Except in special cases, ¹H broad-band decoupling is unnecessary. For very large molecules (metalloproteins), high magnetic field strengths are recommended to cope with second-order shift contributions to the $+\frac{1}{2} \rightarrow -\frac{1}{2}$ quadrupole component. (See Individual Nuclei and Applications, Vanadium, below.)

Commercially available equipment is used for solid-state static, MAS, OFF-MAS and double rotation techniques, and precautions have to be taken to discriminate between resonance signals and rotation side-bands by

measuring the spectra at different spinning frequencies. The information that can be extracted from spectra under the static versus non-static conditions (where quadrupole perturbations, dipole interaction and chemical shift anisotropy effects are suppressed will be exemplified for solid state Sc NMR spectra below. Note again that the position of the central $+\frac{1}{2} \rightarrow -\frac{1}{2}$ transition which, owing to large quadrupole coupling anisotropy often is the only accessible one, is not coincidental with the isotropic shift δ_{iso} .

Table 1 also contains chemical shift reference compounds (used as the zero point of the shift scales) and, in the Table footnote, standards employed in practice, including their chemical shifts with respect to the reference if not identical. Chemical shifts depend on concentration, isotopic composition (in the first but also the second coordination sphere), nature of the solvent, ionic strength, counterion and other influence of the medium, and these dependences are proportional to the intrinsic shielding sensitivity of a nucleus. Where the shielding sensitivity is exceedingly large (⁵⁹Co), these effects are significant and have to be taken into account when preparing sample and standard solutions. Coupling constants are less dependent on medium effects, but relaxation times can also be very dependent on solution conditions.

Other factors influencing shielding (and relaxation times) are temperature and pressure (see below). Chemical shifts should also be corrected with respect to field-lock shifts if different deuterium locks are used for the (external) standard/reference and the sample, and with respect to influences of the bulk susceptibility, if different sample shapes are compared (e.g. cylindrical versus spherical).

Chemical Shifts (Nuclear Shielding)

Figure 1 is a summary of chemical shift ranges for the 3d series nuclei in their more common oxidation states in diamagnetic compounds, representing the present state of knowledge but also, to a certain extent, the intrinsic shielding sensitivities. Shift ranges for high and low oxidation states are represented by open and solid bars, respectively. Metals that form closed shell complexes (d^0 : Sc^{III}; d^{10} : Cu^I, Zn^{II}) have relatively narrow shift ranges, while open shell systems (d^4 : V^I; d^6 : V^{–I}, Mn^I, Fe^{II}, Co^{III}; d^8 : Fe⁰, Co^I) give rise to extended shift ranges. Particularly noteworthy is the overall shift range of $\sim 20\,000$ ppm for ^{59}Co .

There is a tendency for deshielding of the nucleus (downfield shift with respect to the magnetic field, high-field shift with respect to the RF field) in compounds with high-valency metal nuclei, and for shielding in compounds containing the metal nuclei in a low oxidation state. However, as demonstrated by the large overlapping areas of open and solid bars for the same metal in Figure 1, no clear correlation between shielding and oxidation state exists, indicating that the nature of the coordination environment of the metal centre has to

be considered. The factors influencing shielding are complex but can be described in a simplified manner by the expression $\sigma = \sigma(\text{dia}) + \text{const.}(\Delta E^-)_{\text{av}} (C^2 r^{-3})_{\text{av}}$, where σ is the overall shielding and $\sigma(\text{dia})$ the (essentially constant, since dominated by the core electrons) diamagnetic contribution. The second term, the paramagnetic contribution $\sigma(\text{para})$, the main factor influencing variations in shielding (and hence chemical shift), contains the mean HOMO-LUMO splitting ΔE , the LCAO coefficient C of relevant orbitals ($C=1$ in the crystal field approximation), and a measure for the expansion of the orbitals, $\langle r^{-3} \rangle$. The main contributions to this term arise from the valence d orbitals, but in closed shell systems valence p contributions have to be taken into account and may become predominant. Based on this relationship, the following shielding trends can be predicted and have been verified by experiment.

1. A strong ligand field decreases $\sigma(\text{para})$ via an increase of ΔE and thus gives rise to high overall shielding. In compounds with a low-valency metal centre, strong ligands are π acceptors such as CO, PR_3 and CNR; in compounds with a high-valency metal centre, ‘hard’ ligands such as oxo and nitrogen functional groups induce a large ΔE splitting. Consequently, the ^{51}V nucleus is shielded in $[\text{VO}_4]^{3-}$ ($\delta = -540$) as well as in $[\text{V}(\text{CO})_6]^-$ (-1952), and deshielded in $[\text{VS}_4]^{3-}$ ($+1395$) as well as in $[\text{V}(\text{NO})_2(\text{thf})_4]^+$ ($+269$ ppm).
2. Mainly in open shell compounds, shielding is additionally influenced through the $(C^2 r^{-3})_{3d}$ term. This factor becomes small for ligands such as H^- , R^- , I^- , SR_2 or, more generally, for ligands with a high polarizability/low electronegativity. In a series such as $[\text{Co}(\text{NO})_2\text{X}]_2$, shielding increases in the sequence

Figure 1 Chemical shift ranges for the 3d series metals. Open bars correspond to high, solid bars to low oxidation states. Chemical shift values δ have negative signs to the right of the vertical $\delta=0$ line, which connects the references given in Table 1. Where the shift range extends beyond the scale of the figure, the limiting δ values are indicated.

Cl($\delta = +3640$), Br($+3390$), I($+2790$ ppm), known as the ‘normal halogen dependence of chemical shielding’. Corresponding trends (‘normal polarizability dependence’) are commonly found in the series amine, phosphine, arsine and stibine, as well as in the series oxo, thio, seleno and telluro functional ligands. The inverse halogen (polarizability) dependence, i.e. a decrease of shielding (mainly as a consequence of a decrease in ΔE) usually prevails in closed shell d^0 systems; cf. Cp_2TiF_2 ($\delta = -1052$), Cp_2TiCl_2 (-772), Cp_2TiBr_2 (-668 ppm).

3. Bulky ligands and strained ring structures (e.g. 3- and 4-membered chelate rings) induce deshielding in open shell and increase shielding in closed shell systems with respect to sterically normal conditions. This sensitivity of shielding to steric effects often allows for the distinction of conformers and diastereomeric pairs of enantiomers.
4. Non-innocent ligands (typically catecholates, cat) can give rise to substantial deshielding of the metal nucleus, e.g. in $\text{VO}(\text{sb})\text{cat}$ (sb is a tridentate Schiff base dianion) $\delta = +480$ ppm instead of an expected $\delta \approx -540$ ppm for a vanadium compound with an ‘innocent’ N_xO_y donor set.
5. Since the number of relevant transitions between highest occupied and lowest unoccupied molecular orbitals increases with a decrease in local symmetry, structural isomers (e.g. *cis/trans*, *fac/mer*) exhibit different shielding situations.

Secondary Factors Influencing Shielding

Apart from effects arising directly from the coordinating functions and the arrangement of the ligands, various second-sphere and outer-sphere effects have to be considered, some of which will be noted here. (i) Ligand substituents, e.g. Z in phosphines PZ_3 , very effectively influence the steric and electronic nature (donor/acceptor properties) of the ligand. $\text{P}(\text{OR})_3$, for example, induces

stronger shielding than $\text{P}(\text{alkyl})_3$ and PMe_3 stronger shielding than $\text{P}(\text{Bu}^t)_3$. (ii) The shielding variations observed as the counterion or the solvent varies can indicate contact-ion pairing (e.g. in the series $[\text{Co}(\text{en})_3]\text{X}_3$, $\text{X} = \text{Cl}, \text{Br}, \text{I}$: $\Delta\delta = 32$ ppm) and solvation, respectively. (iii) In the solid state, distinct crystallographic sites are represented by distinct resonance signals. The $\delta_{\text{iso}}(\text{solid})$ are not usually equal to $\delta_{\text{iso}}(\text{solution})$.

Isotopic substitution leads to increased shielding for the heavier isotope (e.g. ^{12}CO versus ^{13}CO ; $\text{C}^{14}\text{N}-$ versus $\text{C}^{15}\text{N}-$). This isotope effect can be traced back to the same origin as the temperature and pressure dependence of shielding, i.e. they can be related to the vibrational fine structure of the highest electronic levels participating in electronic transitions: as the temperature decreases, vibronically excited levels become decreasingly populated; ΔE increases, and overall shielding decreases. An equivalent effect is responsible for increased shielding with increased pressure and an increase of shielding for a heavier with respect to a lighter isotopomer. **Table 2** provides selected examples and **Figure 2** illustrates isotope effects for $\text{C}_5\text{H}_5\text{V}(\text{CO})_4$.

Anisotropy of Chemical Shifts

Under anisotropic conditions (solid state, mesophases), the chemical shift consists principally of three components (a parallel ($\delta_{\parallel}$) and two perpendicular ones (δ_1 and δ_2 , where $\delta_{\perp} = \frac{1}{2}(\delta_1 + \delta_2)$), the separation of which depends on the molecular anisotropy which, for quadrupolar nuclei, correlates with the extent of quadrupole perturbation and hence with the size of the nuclear quadrupole coupling constant e^2qQ/b . The extent of anisotropy is expressed by the molecular asymmetry parameter η , defined by $\eta = (\delta_2 - \delta_1)/(\delta_{\parallel} - \delta_{\text{iso}})$, and the chemical shift anisotropy $\Delta\delta = |\delta_{\parallel} - \delta_{\perp}|$. Selected values for δ_{iso} , $\Delta\delta$ and η are listed in **Table 3** together with e^2qQ/b values. The chemical shift anisotropy

Table 2 Isotope, temperature and pressure effects on shielding

Isotope	Compound	Detected by	Isotope shift ^a	Temperature gradient ^b	Pressure gradient ^c

	$[\text{Co}(\text{CN})_6]^{3-}$	^{59}Co	-0.85	1.38	-0.018
	$[\text{Co}(\text{CN})_6]^{3-}$	^{59}Co	-0.197		
$^{14/15}\text{N}$	$[\text{V}(\text{CO})_6]^-$	^{51}V	-0.10		
$^{16/18}\text{O}$	$[\text{MnO}_4]^-$	^{55}Mn	-0.60		

^aThe one- and two-bond isotope shifts are indicated per isotopic substitution.

^bThe temperature gradients (tg) are given in ppm per degree, averaged over a temperature (T) range of $\sim 230\text{--}320$ K (^{51}V) and $290\text{--}350$ K (^{59}Co); the (tg)/ T relation is not strictly linear.

^c kg cm^{-2} , for a pressure range of 1000 to 9000 kg cm^{-2} and at 291 K.

produces an important relaxation mechanism in non-quadrupolar nuclei (^{57}Fe ; see below).

Scalar Coupling Constants

Information on electron-mediated (scalar) spin–spin coupling J may be obtained from the NMR spectrum of the metal nucleus N_M or the ligand nucleus N_L . When N_M is the NMR probe, two limiting cases have to be considered. One case is where coupling is fully effective and thus gives rise to a resolved first-order multiplet for

Figure 2 Two-bond deuterium isotope shifts on the ^{51}V chemical shifts in $\eta^5\text{-}\{\text{C}_5\text{H}_5\text{-}n\text{-}^2\text{H}_n\}\text{V}(\text{CO})_4$ (assigned d_n). The asterisks indicate the high-field components of the natural-abundance ^{13}C satellite doublets for d_0 and d_5 . the M resonance. This is the case if M is a spin- $\frac{1}{2}$ nucleus (^{57}Fe), or if the quadrupole moment of M is small (^{51}V) and L is a spin- $\frac{1}{2}$ nucleus or again a quadrupole nucleus with a small quadrupole moment (^{14}N). Examples are given in **Figure 3a** and **Figure 3b(ii)**. For the medium quadrupole nuclei, resolved J coupling is restricted to compounds where M is in a local symmetry providing small electrical field gradients at the nucleus and hence less effective quadrupole relaxation. The second case is where coupling is completely quenched. This is the case if fast relaxation leads to relaxation decoupling of N_M and N_L , or in the case of intermolecular exchange if it is accompanied by bond rupture. Fast relaxation is encountered with quadrupolar nuclei in all but highly symmetric environments, and with long molecular correlation times τ_c . Bulky and/or large molecules, and a high viscosity of the medium (polar solvents, low temperature, high concentration) will give rise to slow molecular tumbling and hence long τ_c .

If N_L is the NMR probe, we again have to deal with two limiting cases. One is when all of the coupling information is available. This is the case if M belongs to the low quadrupole category nuclei and/or M is at a highly symmetric site. The spectrum appears as a resolved nonbinomial multiplet of multiplicity $2I + 1$ (I is the nuclear spin of M ; **Figure 3b(i)**) or as the envelope of such a multiplet, a typical plateau-like signal where the width at half-height divided by $(2I + 1)$ provides a good estimate for J . In the solid state $J(N_M N_L)$ multiplets can be distorted owing to the anisotropy of J and the quadrupole coupling interaction. An example is $(\text{Ph}_3\text{P})_2\text{CuCl}$, where the ^{31}P quartet spacings are 1.43, 1.27 and 10.94 kHz. The second limiting case is again complete relaxation decoupling, resulting in a comparatively sharp

resonance signal for N_L . More or less broad signals with a Lorentzian–Gaussian line shape are typical for intermediate situations.

Coupling constants $J(\text{N}_M\text{N}_L)$, in most cases one-bond couplings 1J , are available for all of the 3d series nuclei except for ^{67}Zn . They are dominated by the Fermi contact term and the main factors in this term contributing to the size of J are the s electron densities $|S(0)|^2$ at the M and L nuclei, which are susceptible to the metal oxidation state and donor/acceptor properties of the ligands. For a direct comparison of coupling constants of different nuclei, it is advisable to employ the reduced coupling constant $K \propto J/\gamma_M\gamma_L$; γ is the magnetogyric ratio, see **Table 1** for the γ_M values. **Figure 4** summarizes $^1J/\gamma_M\gamma_L$ ranges for various M–L pairs in relation to the $|S(0)|^2$ terms.

Relaxation and Line Widths

The width of a resonance line, usually measured at half-height and quoted as $W_{1/2}$ (or $\Delta\nu_{1/2}$) in units of Hertz, is mainly determined by the spin–spin relaxation time T_2 ($W_{1/2} = (\pi T_2)^{-1}$) which, in nonviscous solutions and other than highly symmetric complexes, usually has about the same magnitude as the spin–lattice relaxation time T_1 . In the solid state, T_1 and T_2 can deviate from each other considerably. The knowledge of T_1 values is a necessary precondition for optimizing NMR detection, especially for nuclei with long T_1 , viz. ^{57}Fe . In the

Figure 4 Reduced one-bond M–L coupling constants versus the product of the s electron densities at the respective nuclei (assuming effective zero charge). Open bars represent M–P (phosphine) coupling; the shaded circle represent phosphites $[\text{P}(\text{OR})_3]$. $S(0)^2$ values have been taken from Pregosin PS and Kunz RW (1979) *NMR Basic Principles and Progress* 16: 80–85.

absence of quadrupolar ligand nuclei, the main relaxation mechanism in ^{57}Fe compounds with a nonisotropic coordination environment is the chemical shift anisotropy $\Delta\delta$: T_1 is inversely proportional to $(\Delta\delta)^2$, the square of the applied magnetic field B_0 and is a function of the correlation time τ_c . τ_c gains importance for large and/or bulky molecules; compare T_1 ($B_0 \approx 9\text{ T}$) = 4.2 s for ferrocene, and 0.02 s for myoglobin · CO.

Chemical shift anisotropy has also been noted for cobalt complexes as a B_0 -dependent component to relaxation which, for quadrupolar nuclei, is otherwise dominated by the quadrupolar relaxation mechanism: $T_2^{-1} \propto f(I)(e^2qQ/b)^2 (1 + \eta^2/3)\tau_c$, where $f(I)$ is a function of the nuclear spin, and e^2qQ/b and η ($= 0$ under axial symmetry) are as defined above (cf. also **Table 2**). τ_c describes the intimacy of interaction between solvent and solute molecules and hence the ease by which a solute molecule tumbles in a solution. As noted previously, T_1 and T_2 are very similar. For example, in aqueous ZnSO_4 , ^{67}Zn T_1 and T_2 are 9.3 and 9.8 ms; in aqueous $\text{Co}(\text{acac})_3$ the ^{59}Co T_1 and T_2 are both 1.7 ms, and in neat VOCl_3 its ^{51}V T_1 and T_2 are both 17 ms while the ^{50}V T_1 and T_2 are both 5 ms. The latter example (VOCl_3) clearly demonstrates the importance of the size of the nuclear quadrupole moment Q (cf. **Table 1**), since all of the other parameters are identical. On the other hand, in a series of similar compounds containing the same metal nucleus (i.e. the same $f(I)$ and Q), T_2 reflects variations of τ_c and the electric field gradient q at the nucleus. For solutions, long T_2 (narrow resonance lines) can hence be expected for nuclei with a reasonably small Q (e.g. ^{51}V), for small, nonbulky molecules in nonviscous media (influence via τ_c), for molecules of cubic point symmetry and for a few other cases where q becomes small, e.g. octahedral complexes of C_{3v} symmetry, half-sandwich complexes having local C_{3v} or

C_{4v} symmetry, or trigonal-pyramidal complexes of C_{3v} symmetry. The field gradient q also reflects the donor and acceptor power and related properties of the ligands.

Finally, it should be remembered that relaxation is also influenced by chemical exchange.

Individual Nuclei and Applications

Scandium and Titanium

Scandium-45 is a relatively easily accessible nucleus owing to its 100% natural abundance and high magnetogyric ratio, but the comparatively large quadrupole Q has restricted its application. In the solid state, the large Q can provide valuable information on the quadrupolar interaction as exemplified for $\text{ScCl}_3 \cdot 6\text{H}_2\text{O}$ and $\text{Sc}(\text{O}_2\text{CCH}_3)_3$ in **Figure 5**. Relevant data can be extracted from static spectra, which depending on the strength of the applied magnetic field, reveal first-order or second-order quadrupole patterns (**Figure 5b**), while under MAS conditions (**Figure 5c**) the main spectral information is the exact isotropic chemical shift.

The concentration, counterion and pH dependences of $\delta(^{45}\text{Sc})$ in aqueous solutions of scandium salts have revealed equilibria between outer-sphere versus inner-sphere complexes (contact ion pairs versus direct coordination of the anion), in addition to the equilibria between $[\text{Sc}(\text{H}_2\text{O})_6]^{3+}$, which is present at low pH, its deprotonation $[\text{Sc}(\text{H}_2\text{O})_5(\text{OH})]^{2+}$ and oligomerization products $[\text{Sc}_2(\text{H}_2\text{O})_x(\text{OH})_2]^{4+}$, $[\text{Sc}_3(\text{H}_2\text{O})_y(\text{OH})_4]^{4+}$, present at pH values up to 4, and $[\text{Sc}(\text{OH})_4]^-$, the species that is formed at high pH.

Owing to the very similar magnetogyric ratios, for $^{47/49}\text{Ti}$, NMR spectra are twinned, the two resonances separated by only 266 ppm. The slightly smaller Q and larger spin of the ^{49}Ti nucleus make the low-field

Figure 5 Solid state ^{45}Sc NMR spectra. a: Static of $\text{ScCl}_3 \cdot 6\text{H}_2\text{O}$ at 8.45 T; b: static of $\text{Sc}(\text{O}_2\text{CCH}_3)_3$ at 3.52 T; c: MAS of $\text{Sc}(\text{O}_2\text{CCH}_3)_3$ at 8.45 T, showing the central line and spinning side-bands. (high-frequency) twin the better-resolved one. As in the case of ^{45}Sc , the sizeable quadrupole moments restrict the observability of $^{47/49}\text{Ti}$ resonances to rather symmetric molecules. $[\text{Ti}(\text{CO})_6]^{2-}$ marks the high-field, TiI_4 the low-field margin of the Ti chemical shift scale. Mono- and bis(cyclopentadienyl) complexes are in between. In the context of their application in Ziegler–Natta polymerization, a dependence of chemical shift upon the electronic nature of the substituents on cyclopentadienyl (Cp) is noteworthy, an effect which is also observed for $\delta(^{51}\text{V})$ and $\delta(^{57}\text{Fe})$ in Cp–vanadium and Cp–iron complexes.

Vanadium, Chromium and Manganese

The nucleus ^{51}V is the only one among the quadrupolar transition metals with a relatively low quadrupole moment *and* a high receptivity, and is hence a particularly well-suited NMR probe even in compounds with no actual symmetry. Well-resolved coupling patterns, however, require compounds of medium to high local symmetry, as shown in **Figures 2** and **3** for complexes of idealized C_{4v} , Δ_{4h} and T_d symmetries. A large body of J and δ data has been accumulated (see Further Reading for compilations), many of them in the context of investigations into biological/biomimetic vanadium systems, vanadium catalyst systems, correlations between NMR parameters and ligand properties, and vanadium speciation analysis.

More than a dozen species have been detected in aqueous vanadate solutions, and their interconversion

and protonation/deprotonation equilibria have been studied by quantitative 1D-NMR, 2D-EXSY, and a combination of ^{51}V NMR with potentiometric measurements. The latter procedure has turned out to be a powerful tool for investigating the speciation in ternary systems containing, along with vanadates and protons, a biogenic ligand as a third component. **Figure 6** is an illustrative example for such a system. While the extreme narrowing conditions ($\omega\tau_c \ll 1$) are fulfilled in these systems, this is no longer so for large V^{V} –protein molecules with a tightly bound vanadium, placing the vanadium outside the extreme narrowing (though still within the motional narrowing) regime. Here, acquisition of spectra is restricted to the quadrupolar central $+\frac{1}{2} \rightarrow -\frac{1}{2}$ transition, which makes up only about 20% of the overall intensity (and is subject to a second-order shift contribution) but, contrasting the other three quadrupole components, does not suffer from severe relaxation broadening. The two slightly different metal ion binding sites in the C- and N-terminal lobes of transferrin have thus been characterized by ^{51}V NMR.

The main oxidation states investigated by ^{51}V NMR are the diamagnetic $-I$ (carbonylvanadates), $+I$ (half-sandwich complexes) and $+V$ states (e.g. vanadates and other oxovanadium(V) compounds), but other oxidation states such as $-III$, low-spin $+III$ and binuclear, and strongly antiferromagnetically coupled $+IV$ have also been studied. Irrespective of the oxidation state, the concepts of electronic and steric ligand influences upon $\delta(M)$ outlined above are valid throughout. The steric

Figure 6 pH-dependent 131.5 MHz ^{51}V NMR spectra of the system vanadate/ H^+ / alanylhistidine (Ah). The resonances correspond to decavanadate (V_{10}), vanadate–Ah complexes (V–Ah), monovanadate (V_1), divanadate (V_2), tetravanadate (V_4) and pentavanadate (V_5) in chemical equilibrium with each other. Reproduced with permission from Elvingsn K, Fritzsche M, Rehder D, and Pettersson L (1994) Potentiometric and ^{51}V NMR study of aqueous equilibria in the H^+ –vanadate(V)–alanylhistidine system. *Acta Chimica Scandinavica* 48: 881.

effect has been employed to distinguish between diastereomers based on pairs of enantiomers in V^I and V^V complexes. Depending on the separation of the chiral centres, the diastereomer splittings amount to $\sim 2 - 10$ ppm.

Chemically there are many similarities between V, Cr and Mn in their low-valency diamagnetic states (d^6 : V^{-I} , Cr^0 , Mn^{+I}) and in their highest, closed shell (d^0) oxidation states. Where data are available (mainly for $Cr-d^6$ and $Mn-d^6$), dependences of chemical shifts $\delta(^{53}Cr)$ and $\delta(^{55}Mn)$ upon the donor/acceptor properties and sensitivities towards steric effects have been documented that parallel those reported for $\delta(^{51}V)$ in $V-d^6$ and $V-d^4$ complexes.

The relative receptivity of the ^{55}Mn nucleus compares with that of ^{51}V ; $Q(^{55}Mn)$ is, however, an order of magnitude larger than $Q(^{51}V)$, limiting the accessibility of ^{55}Mn as an NMR probe. The manganese shift range is flanked by $[Mn(CO)_3(NCMe)_3]^+$ at the low-field margin, and the formally Mn^{-III} complexes $Mn(NO)_3L$ at the high-field margin. The only Mn^{VII} compound studied so far by NMR is $KMnO_4$, which gives a very sharp resonance line in solution in accordance with its T_d symmetry but a very broad feature in the solid state as a consequence of effective interaction between Q and a crystallographically imposed field gradient q . For $|Q(^{53}Cr)|$, reported values range between 0.04 and $0.15 \times 10^{-28} m^2$. NMR experience with this nucleus places it in the medium quadrupole category which, along with the low receptivity, makes ^{53}Cr a difficult nucleus to detect. The $\delta(^{53}Cr)$ shift range is flanked by $[CrO_3Br]^-$ (+670) and *cis*- $[Cr(CO)_2(PF_3)_4]$ (−1898 ppm).

Iron, Cobalt and Nickel

Iron-57 ($I = \frac{1}{2}$) is among the least NMR-sensitive nuclei of the periodic table. Isotopic enrichment or steady-state techniques (in the case of long T_1), high magnetic field strengths and large sample volumes may be applied in the case of direct detection, but 1D double resonance and 2D indirect techniques are nowadays much more commonly employed in spectrum acquisition wherever coupling to a sensitive ligand nucleus in the coordination sphere (such as 1H , ^{13}C , ^{15}N , ^{31}P) is observable. The chemical shift range spanned by ^{57}Fe , $\sim 12\,000$ ppm, is surmounted only by the ^{59}Co shift range of $\sim 20\,000$ ppm. In the case of ^{59}Co , this extended shift range, reflecting a high intrinsic shielding sensitivity, somewhat neutralizes the disadvantage of the relatively large $Q(^{59}Co)$, leading to line widths commonly of several kHz. Nonetheless, abundant data on hexa- and tetracoordinated cobalt complexes in the oxidation states +III, +I and −I are in fact available. In contrast, ^{61}Ni , again a medium quadrupole category nucleus, but with a

very low receptivity, causes severe detection problems. Only relatively recently, through the use of special devices such as solenoidal coils, has a comprehensive series of NMR parameters been obtained on mixed phosphine/carbonylnickel(0) (d^8) complexes, which exhibit chemical shift dependences on the nature of the substituents Z in the phosphine PZ_3 comparable to what is known from open shell complexes of other transition metals.

Recent applications of ^{57}Fe and ^{59}Co NMR have been directed towards correlations between chemical shift and kinetic parameters on the one hand and the investigation of iron–porphyrin and cobalt–porphyrin systems on the other. In the half-sandwich complexes $CpFe(CO)_2R$ ([1] in Figure 7) shielding decreases with increasing bulk of R ($\delta(^{57}Fe)$ values cover the range of +684 for R = Me to +805 for R = Bu^s), and $\delta(^{57}Fe)$ in turn correlates linearly with the rate constant k for the insertion of CO in the reaction

(increase in k as shielding decreases). The sensitivity of shielding to steric effects is also evident in the discrimination of conformers of the complexes (diene) $Fe(CO)_2L$ [2]. The catalytic activity of the complexes $Cp'Co(diene)$ ([3] in Figure 7) in the formation of substituted pyridines [4] by co-trimerization of alkynes and isonitriles is closely related to $\delta(^{59}Co)$, which in turn is related to the nature of Cp' : an electron-rich Cp' , such

Figure 7 Applications of ^{57}Fe and ^{59}Co NMR. For compounds [1] $\delta(^{57}Fe)$ values correlate with the size of R and the rate of insertion of R into the Fe–CO bond. Compounds [2] are different conformers discernible by their $\delta(^{57}Fe)$ values. Compounds [3] catalyse the formation of [4]; the ratio of [4a] and [4b] depends on the $\delta(^{59}Co)$ values, which are related to the nature of R.

as C_5Me_5 gives rise to high shielding of the ^{59}Co nucleus and induces the preferred formation of the symmetrically substituted pyridine [4a].

The presence in porphyrin and related systems of cobalt (cobalamines) and iron (heme proteins) has initiated metal NMR studies into native (myoglobin, cytochrome *c*) and model systems (substituted porphyrins) with the objective of elucidating the influence of the chemical nature of axial ligands (CO, isonitriles, N-donors) upon parameters such as δ and T_1 (and e^2qQ/b in the case of ^{59}Co), and hence of the functionally interesting metal centre. The differing binding strengths of isonitriles and carbon monoxide in myoglobins produce a change of the chemical shift anisotropy (CSA), viz. $\Delta\delta = 3600$ ppm for Mb·CO versus 1250 ppm for Mb·CNR, and thus clearly different CSA-induced T_1 values (17 ms for Mb·CO, 140 ms for Mb·CNR).

Copper and Zinc

Cu^+ and Zn^{2+} are closed shell d^{10} systems and exhibit relatively low intrinsic shielding sensitivities. This fact, together with the unfavourable size of the quadrupole moment, the low receptivity in the case of ^{67}Zn , and the ease of chemical exchange in the case of Cu complexes, has restricted NMR access to these biologically important metal nuclei. The $\delta(^{63/65}\text{Cu})$ range spans ~ 1000 ppm, with an extension from the high-field margin (-517 ppm, occupied by $[\text{CuI}_4]^{3-}$) to -2494 ppm for the cluster compound $[\text{Cu}_3\text{Fe}_3(\text{CO})_{12}]^{3-}$. ^{67}Zn chemical shifts encompass about 450 ppm. Cu^{I} complexes with N-donor ligands such as nitriles and pyridines undergo exchange of the kind $[\text{CuL}_4]^+ \rightleftharpoons [\text{CuL}_3]^+ + \text{L}$, where the lower symmetry component considerably broadens the resonance line. Despite this complication, some insight has been obtained by ^{63}Cu NMR into the distribution of Cu^+ in

mixed-solvent systems comprising nitriles and phosphites. A few series of tetrahedral Cu and Zn complexes, viz. $[\text{Cu}(\text{phosphite})_4]^+$, $[\text{Cu}(\text{ER}_2)_4]^+$ ($\text{E} = \text{S}, \text{Se}, \text{Te}$) and $[\text{Zn}(\text{ER}_2)_4]^{2+}$ ($\text{E} = \text{S}, \text{Se}$) have been investigated. The latter are of interest in the context of biogenic $\{\text{ZnCys}_4\}$ centres present in alcohol dehydrogenase and thioneins.

The $^{63/65}\text{Cu}$ probe is also increasingly used to elucidate solid-state features of copper-containing superconducting materials.

The elements yttrium (Y), zirconium (Zr), niobium (Nb), molybdenum (Mo), technetium (Tc), ruthenium (Ru), rhodium (Rh), palladium (Pd), silver (Ag) and cadmium (Cd) form a series of transition metals characterized by the electronic configurations $Kr4d^n5s^2$ where $n = 1-10$. This series of d-block metals is located in the 5th row of the periodic table, between the series from Sc to Zn (4th row) and from La to Hg (6th row). The NMR spectroscopy of transition metals is a rapidly increasing area of magnetic resonance with new experimental methods and new applications for both the solution and, especially, for the solid state. There is an extensive literature on multinuclear NMR studies applied to the structures of polyoxometalates of many transition metal nuclei, especially Nb and Mo. The NMR data available for the series from Y to Cd depends strongly on the element. A literature search using the *Chemical Abstracts* data base reveals that in case of Y, Zr, Tc, Ru and Pd the number of reports is limited while for ^{113}Nb , ^{95}Mo , ^{103}Rh and ^{113}Cd there exists much experimental data. Cadmium-113 alone makes up about 20% of the total NMR papers dealing with these d-block metals. However, this situation might change significantly in the future. For example, with the advent of high temperature superconductors one might expect that ^{89}Y NMR could become a very common method in characterizing yttrium-containing superconducting materials.

Generally, in this article the main aim is to cover novel NMR techniques and promising new results, supplemented with characteristic reference data available in the excellent reviews and articles catalogued in the Further Reading section at the end of this article. In selecting and arranging the reference material it has been the goal to demonstrate obvious trends in NMR data (mainly collected in tables of characteristic chemical shifts) that depend on the structural characteristics and measuring

conditions: solution vs. solid state, the ligand in a metal complex and its substitution, coordination number, solvent, temperature, etc. From these tables the reader can get a hint as to where to hunt for a 'hidden' NMR signal. The text itself, dedicated to each of the NMR-nuclei concerned, serves as a general guide to select an appropriate measuring technique and to estimate if it is worth examining a given NMR-nucleus when compared with the other possible nuclei and techniques available.

Properties of the Nuclei

Some important properties of the NMR active isotopes of Y, Zr, Nb, Mo, Tc, Ru, Rh, Pd, Ag and Cd are collected in Table 1. From the practical point of view the receptivity (R) relative to that of ^{13}C ($=1$) is one of the most important terms in estimating how easily a nucleus can be observed by NMR. In the case of nuclei with $I = \frac{1}{2}$ such as ^{89}Y , ^{103}Rh , ^{107}Ag , ^{109}Ag , ^{111}Cd and ^{113}Cd , which are characterized by sharp NMR spectral lines, this parameter can be used as a direct basis in this estimation. However, a nuclear quadrupole moment can produce serious broadening of the spectral lines and hence decrease the signal-to-noise ratio in the NMR spectra. In the case of transition metal nuclei this signal broadening can be the most serious limiting factor from a practical NMR point of view. For example, ^{105}Pd should be a promising NMR nucleus based on its receptivity and natural abundance but it suffers from a huge nuclear quadrupole moment such that in, for example, K_2PdCl_6 the line width at half-height is 25 kHz. Other limiting factors often met in the early days of NMR, viz. the limited spectral range of the spectrometer hardware, probe and amplifiers, are nowadays not usually problematic. A modern NMR spectrometer can be tuned and matched routinely to observe nuclei from ^{103}Rh to ^{31}P , ^{19}F and ^1H . This flexibility and the increased sensitivity of NMR spectrometers, e.g. inverse 2D detection techniques, are pushing the detection limits of transition metal nuclei to small concentrations and allowing complex structural characterizations.

Experimental Methods

The variety of measuring techniques and applications in heteronuclear NMR is enormous. In the case of $I = 1/2$

Table 1 Isotope, spin (I), Natural abundance (%NA), frequency (B_0) relative to ^1H (at 100 MHz), receptivity (R) relative to ^{13}C ($=1$), magnetogyric ratio (γ), magnetic moment (μ) and nuclear quadrupole moment (Q_m^2)

Isotope	I	NA (%)	B_0	R	$10^7 (\gamma \text{ rad T}^{-1} \text{ s}^{-1})$	μ	$10^{28} Q (\text{m}^2)$
^{89}Y	$-\frac{1}{2}$	100	4.92	0.67	– 1.31	– 0.137	–
^{91}Zr	$-\frac{1}{2}$	11.2	9.37	6.05	– 2.50	– 1.304	– 0.21
^{93}Nb	$-\frac{1}{2}$	100	24.55	2740	6.54	6.17	– 0.32
^{95}Mo	$-\frac{1}{2}$	15.9	6.52	2.88	1.74	– 0.914	– 0.015
^{97}Mo	$-\frac{1}{2}$	9.55	6.65	1.84	– 1.78	– 0.934	0.17
^{99}Tc	$-\frac{1}{2}$	0	22.5	–	6.05	5.66	– 0.13
^{99}Ru	$-\frac{1}{2}$	12.7	3.39	0.82	– 1.23	– 6.41	0.076
^{101}Ru	$-\frac{1}{2}$	17.0	4.94	1.54	– 1.38	– 0.719	0.44
^{103}Rh	$-\frac{1}{2}$	100	3.17	0.18	– 0.85	– 0.088	–
^{105}Pd	$-\frac{1}{2}$	22.3	4.58	1.43	– 0.76	– 0.642	0.8
^{107}Ag	$-\frac{1}{2}$	51.8	4.05	0.20	– 1.08	– 0.113	–
^{109}Ag	$-\frac{1}{2}$	48.2	4.65	0.28	– 1.24	– 0.131	–
^{111}Cd	$\frac{1}{2}$	12.8	21.2	7.01	– 5.70	– 0.595	–
^{113}Cd	$\frac{1}{2}$	12.2	22.2	7.59	– 5.93	– 0.622	–

nuclei the same basic rules as for ^1H , ^{19}F and ^{13}C are true. However, one should remember that negative gyromagnetic ratios as in case of silver–107/109 and cadmium–111/113 isotopes prevent the signal enhancement by NOE effects. This is different to the case for ^{13}C NMR. For $I \geq 1$ nuclei the nuclear quadrupole moment opens an efficient relaxation channel and magnetization (free induction) decays often very rapidly. Starting the acquisition as soon as possible after the excitation pulse to avoid the loss of magnetization causes some distortions on the spectral base line (rolling) owing to the acoustic ringing of the probehead. This distortion can be eliminated by ‘an antiringing’ pulse sequence (at the expense of sensitivity) or by using base line correction routines that are now available as a standard in the spectrometer software.

Two-dimensional experimental techniques such as homo- and heteronuclear chemical shift correlations are frequently used in heteronuclear NMR applications. COSY (correlation spectroscopy) and INADEQUATE (incredible natural abundance double quantum transfer experiment) are suitable methods if the natural abundance is not very low, as in the case of ^{113}Cd . The most promising 2D techniques are, however, inverse detected heteronuclear chemical shift correlations such as $^1\text{H}, \text{X}$ HSQC (heteronuclear single quantum coherence), $^1\text{H}, \text{X}$ HMQC (heteronuclear multiple quantum coherence) and $^1\text{H}, \text{X}$ HMBC (heteronuclear multiple bond correlation) and, especially, $^{31}\text{P}, \text{X}$ HMQC and $^{31}\text{P}, \text{X}$ HMBC. If the scalar coupling constants between a proton (phosphorus or any nucleus of high natural abundance and high gyromagnetic ratio used for free induction decay (FID) detection) and the heteronucleus is small (< 2 Hz), the delay in the evolution of these couplings increases to such a length that a significant loss of magnetization occurs and inverse heteronuclear multiple quantum (or

bond) correlation becomes impractical. Using the proton for detection of heteronuclear chemical shift correlation can be done easily by a standard two-channel spectrometer equipped with a direct or inverse dual (proton and X) probehead. To observe heteronuclear chemical shift correlation by ^{31}P or some other heteronucleus the spectrometer should have two broadband channels and a triple resonance probehead to be able to perform proton decoupling during an experiment if necessary.

Low natural abundances, low gyromagnetic ratios and high quadrupole moments of several NMR-active isotopes of the series from yttrium to cadmium can cause difficulties in solution state NMR. However, these formidable obstacles in the solution state can be turned to advantages in solid state NMR. Low natural abundance (i.e. dilute spins) can help in solid state measurements because the problem raised by dipolar interactions between like spins is eliminated. Sensitivity problems found with low gyromagnetic ratios in the solution state can be overcome in the solid state by the cross-polarization (CP) technique by which the magnetization of the observed nucleus (S) can be increased by a factor, $\gamma_{\text{H}}/\gamma_{\text{S}}$. Further, a nuclear quadrupole moment can result in considerable sensitivity to local nuclear site symmetry, thus giving useful structural information.

The major technique to eliminate dipolar interactions in the solid state NMR is MAS (magic-angle spinning). Together with CP and high-power proton decoupling it has become the most often applied method in solid state NMR. However, in this connection it is worth mentioning some other techniques such as double-rotation (DOR) and dynamic-angle spinning (DAS) which could remarkably increase the potential of the NMR of quadrupolar nuclei in the future. In DOR, MAS and DAS techniques the sample must be rotated at high speed, which can cause some technical problems. These are

Table 2 Some characteristic ^{89}Y NMR chemical shifts from $[\text{Y}(\text{H}_2\text{O})_6]^{3+}$ ($\delta = 0$ ppm)

Compound	Solvent/conditions	δ (^{89}Y)/(ppm)
$\text{Y}(\text{NO}_3)_3$	0.77 M in H_2O – OCMe_2 at 298 K	– 4.9

^a $\text{Cp}' = \text{C}_5\text{H}_4\text{Me}$, THF = tetrahydrofuran.

avoided by manipulation of nuclear spins by pulse sequences such as two-pulse free induction decay (TPF) and nutation spectroscopy. 2D NMR nutation spectroscopy of powder samples has been applied, for example, in ^{93}Nb NMR.

Yttrium-89

Although ^{89}Y is characterized by $I = \frac{1}{2}$, its long T_1 relaxation time, low magnetic moment and low measuring frequency have caused problems in ^{89}Y NMR. On the other hand, its 100% natural abundance and the increasing interest in organo-yttrium and solid state chemistry (high-temperature superconducting materials, e.g. $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$) have created strong interest in this NMR nucleus. Especially promising in this respect is the CP-MAS technique. At first, CP-MAS was applied in the case of the 'common' NMR nuclei such as ^{13}C , ^{27}Al , ^{29}Si and ^{31}P but has now expanded into 'more difficult' low γ -nuclei such as ^{89}Y . The first solid state ^{89}Y CP-MAS NMR spectra of $\text{Y}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$, $\text{Y}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$, $\text{YCl}_3 \cdot 6\text{H}_2\text{O}$, $\text{Y}(\text{OAc})_3 \cdot 4\text{H}_2\text{O}$ and $\text{Y}(\text{acac})_3 \cdot 3\text{H}_2\text{O}$ were reported by Merwin and Sebald in 1990. Later, mono-, di- and polymetallic samples were characterized by ^{89}Y CP-MAS NMR, revealing a direct correlation between the number of ^{89}Y NMR signals and the unique solid state environments of the ^{89}Y nuclei.

In Table 2 are collected some characteristic ^{89}Y NMR chemical shifts. Nowadays, a common reference compound for ^{89}Y NMR is aqueous $\text{Y}(\text{NO}_3)_3$ although aqueous YCl_3 also has been used. In fact, both salts form, in water, the same hexahydrate cation, $[\text{Y}(\text{H}_2\text{O})_6]^{3+}$. Generally, the chemical shifts of the yttrium salts show similar concentration trends to those observed for scandium and lanthanum.

Zirconium-91

The number of papers dealing with ^{91}Zr NMR is still small. However, some ^{91}Zr NMR chemical shifts of

Table 3 Some characteristic ^{91}Zr NMR chemical shifts from Cp_2ZrBr_2 ($\delta = 0$ ppm)

Compound	Solvent	δ (^{91}Zr)/(ppm)
$\text{Zr}(\text{NEt}_2)_4$	–	+ 875
$\text{Zr}(\text{BH}_4)_4$	Benzene- d_6	+ 41

$\text{Cp}_2\text{ZrCl}(\text{vinyl})$	THF ^b	+ 16
$\text{CpZr}(\eta^3\text{-allyl})(\text{ip})^d$	–	+ 132
$\text{Cp}_2\text{Zr}(\text{ip})$	–	– 325

^a $\text{Cp} = \text{C}_5\text{H}_5$.

^bTHF = tetrahydrofuran.

^c $\text{Cp}^* = \text{C}_5\text{Me}_5$.

^d $\text{ip} = \eta^4$ -isoprene.

organometallic compounds (mainly zirconocene derivatives) and inorganic ions are available and are collected in Table 3. The line widths, $LW_{1/2}$, of these compounds vary between 19–3100 Hz. The most often used standard is Cp_2ZrBr_2 because it shows a sharper resonance line than any other zirconium complex. Von Philipsborn and co-workers (Organisch-Chemisches Institut, Universität Zürich) have used zirconium-91 NMR chemical shifts and line widths as indicators of coordination geometry distortions in zirconocene complexes. Further, the experimental trends in ^{91}Zr NMR chemical shifts of these zirconocene complexes are well reproduced computationally by molecular orbital calculations using the IGLO (individual gauge for localized orbitals) or GIAO (gauge including AOs) SCF methods employing large basis sets. In the solid state, Zr-metal, ZrH_2 , ZrC , ZrCo , ZrO_2 and ZrO_2 doped with Y_2O_3 and MgO have been characterized by ^{91}Zr NMR. Solid state ^{91}Zr NMR line shapes have been found to be related to the Zr (or Nb) content in $\text{Zr}_{1-x}\text{Nb}_x$ alloys. These applications suggest an

increasing interest in ^{91}Zr NMR in metallurgy and material sciences.

Niobium-93

There exist several reports on ^{93}Nb NMR, as expected based on a natural abundance of 100% and a receptivity of 2740 (Table 1). In fact, the receptivity of ^{93}Nb is one of the most promising among all the NMR-active nuclei. However, the influence of broad resonance lines again effectively diminishes its usefulness although its other NMR-properties are favourable. In Table 4 are collected some characteristic ^{93}Nb NMR chemical shifts. In general the chemical shift trends of ^{93}Nb are similar to those observed for ^{51}V NMR. Recommended reference compounds for niobium-93 are NbOCl_3 in acetonitrile or the $[\text{NbF}_6]^-$ anion in concentrated aqueous HF, although $[\text{NbCl}_6]^-$ in acetonitrile has also been used. In addition to inorganic salts and their anions, and various carbonyl niobium complexes collected in Table 4 there exist several cyclopentadienyl niobium complexes. The ^{93}Nb NMR chemical shifts of these organometallic complexes are clearly shielded, varying between 1290 and 2258 ppm upfield from the reference. Their $LW_{1/2}$ vary from 20 Hz for $\text{CpNb}(\text{CO})_4$ in $\text{THF}-\text{CH}_2\text{Cl}_2$ to 10 300 Hz in $[\text{CpNb}(\text{AuPPh}_3)(\text{CO})_3]^-$.

In addition to the previously mentioned 2D nutation NMR spectroscopy, an interesting method in solids, first-satellite spectroscopy, applied to ^{93}Nb NMR of LiNbO_3 (and ^{27}Al NMR in Al_2O_3) has been reported by McDowell and his co-workers. This technique is experimentally easier and more sensitive than the other methods for studying wide, quadrupolar broadened spectra. Further, the experimental data are considerably

simpler and easier to interpret than obtained by the other methods. Examples of the significance of ^{93}Nb NMR in materials science include novel solid state studies on ion ordering and ion shifts in relaxor ferroelectrics, structural distortions and intrinsic defects in LiNbO_3 and studies on superconducting Nb–Cu multilayers by the field cycling method.

Molybdenum-95 and -97

Molybdenum has two naturally abundant NMR-active isotopes (Table 1). The nuclear properties of the isotope ^{95}Mo are more favourable than those of ^{97}Mo . Malito has reviewed more than 150 original papers on ^{95}Mo NMR. The vast majority of those reports are solution state studies whilst very few of them deal with solid state $^{95/97}\text{Mo}$ NMR. This scarcity of solid state $^{95/97}\text{Mo}$ NMR data results from the relatively low NMR receptivity, long probe dead-times and acoustic ringing associated with the pulse-NMR observation of these low-frequency isotopes. More recently, however, it has been demonstrated that solid state MAS ^{95}Mo NMR studies of organometallic complexes of molybdenum are feasible, particularly if the compounds are known to give relatively narrow ^{95}Mo NMR spectral lines in solution.

As mentioned before (poly)oxometalates and related structures are traditional topics for multinuclear NMR studies. In the case of molybdenum, there exist systematic experimental NMR and *ab initio* molecular orbital studies on $[\text{MoO}_{4-n}\text{X}_n]^{2-}$ anions ($\text{X} = \text{S}$ or Se and $n = 0-4$). It has been shown that the ^{95}Mo NMR chemical shifts of these anions can be reliably estimated by such calculations. The paramagnetic shielding term mainly determines the chemical shift variation, ligand induced changes in molybdenum valence d-orbitals correlate with the changes in the metal chemical shift and the excitation energy term, ΔE , in the Karplus–Pople equation is related to the character of the ligand.

Some characteristic ^{95}Mo NMR chemical shifts are collected in Table 5. A common reference for ^{95}Mo NMR is aqueous (0.2 M) Na_2MoO_4 ($\delta = 0$ ppm). The chemical shift variation of ^{95}Mo is from +4000 to –2000 ppm and clearly depends on the oxidation state of the metal. ^{95}Mo NMR line widths can be very broad (> 5 kHz). Generally, slower molecular motion (as a consequence of increased relative molecular mass) results in broader resonance lines. This fact can be a limiting factor in studies of molybdenum-containing metalloenzymes and other biopolymers by ^{95}Mo NMR. A more recent area of biochemical interest is the Mo(VI) complexes of carbohydrates such as alditols and corresponding acids. For example, it has been shown by ^1H , ^{13}C , ^{17}O and ^{95}Mo NMR that D-galacturonic and D-glucuronic acids in their aqueous solutions form

complexes with molybdate anions. Although the acids predominately exist in the pyranose forms, their complexes involving the less stable α - and β -furanose anomers as well as the α -pyranose form were detected also. The 2:1 complexes with the α -pyranose forms, insofar as they involve metal binding to the ring oxygen atom, are considered to play an important role in the oxidation of the acids by Mo(VI) .

Tchnetium-99

Tchnetium is an artificially produced element used for medical imaging. Reports dealing with ^{99}Tc NMR are very rare. In addition to unfavourable NMR properties (Table 1) a more complex situation regarding practical measurements comes from the fact that ^{99}Tc is radio-active. Nevertheless, there are some ^{99}Tc NMR chemical shifts available, as collected in Table 6, referenced to the signal of TcO_4^- ($\delta = 0$ ppm). ^{99}Tc NMR line widths can vary strongly from <100 Hz to >3 kHz.

Ruthenium-99 and -101

Ruthenium has seven stable isotopes, of which ^{99}Ru and ^{101}Ru are NMR active. Although their natural

^a1,2-Bis(dimethylphosphino)ethane.

abundances and resonance frequencies are quite similar, the smaller quadrupole moment of ruthenium-99 makes the former more favourable from an NMR spectroscopic point of view. The ^{99}Ru NMR chemical shift range is enormous (>18 000 ppm). The shifts of ruthenium compounds and complexes follow roughly the same trends as those of iron and osmium. The reference compound in ^{99}Ru NMR is the $[\text{Ru}(\text{CN})_6]^{4-}$ anion ($\delta = 0$ ppm). Some characteristic ^{99}Ru NMR chemical shifts are collected in Table 7.

Ruthenium complexes with nitrogen-containing ligands show very interesting photochemical properties which can be monitored by ^{99}Ru NMR. In materials science, solid state ^{99}Ru and ^{101}Ru NMR has been applied in characterizing the packing of ruthenium metal. This

result represents the first detection of Ru NMR in a paramagnetic solid.

Rhodium-103

Traditionally ^{103}Rh NMR spectroscopy has been regarded as problematic owing to the very low gyromagnetic ratio and long relaxation time of rhodium-103 although its natural abundance is 100% and $I = \frac{1}{2}$ (Table 1). However, by using modern broadband spectrometers rhodium-103 is an easy nucleus to observe. Taking into account the catalytic significance of rhodium compounds, ^{103}Rh NMR spectroscopy has turned out to be a very powerful method and there exist plenty of experimental data. Some characteristic ^{103}Rh NMR chemical shifts are collected in Table 8. In the case of ^{103}Rh NMR, several chemical shift references have been used but nowadays *mer*- $[\text{RhCl}_3((\text{SCH}_3)_2)_3]$ is generally accepted. Owing to the low gyromagnetic ratio of rhodium-103, its detection is now based on polarization transfer techniques such as INEPT (insensitive nuclei enhanced by polarization transfer), DEPT (distortionless enhancement by polarization transfer) or HMQC although earlier INDOR (internuclear double resonance)

Figure 1 ^{31}P , ^{103}Rh HMQC spectrum obtained from a mixture of $[\text{Rh}(\text{H})(\text{PPh}_3)_4]$ (0.02 M), CySH (0.2 M) and Ph_3P (0.2 M) in 10% pyridine–toluene at -25°C . Reproduced with permission of John Wiley and Sons from Carlton L (1997) Rhodium–103 NMR of carboxylate and thiolate complexes by indirect detection using phosphorus. *Magnetic Resonance in Chemistry* 35: 153–158. Copyright 1997, John Wiley & Sons.

was also utilized. If a rhodium-bound proton is used for the detection of rhodium-103, an enhancement of $(\gamma_{\text{H}}/\gamma_{\text{Rh}})^{5/2} = 5635$ can be achieved in ^1H , ^{103}Rh HMQC. If the proton is not directly bound to rhodium and ^1H , ^{103}Rh HMBC must be used instead of HMQC; the delay required for polarization transfer [generally $J(^1\text{H}, ^{103}\text{Rh}) \leq 2$ Hz] is so long that an extensive loss of magnetization occurs. The magnitude of $^1J(^{31}\text{P}, ^{103}\text{Rh})$ is generally not less than 80 Hz and therefore ^{31}P is an excellent nucleus for indirect detection of rhodium NMR resonances although the enhancement by differences in gyromagnetic ratios is not as favourable as in the case of proton. Figure 1 shows the ^{31}P , ^{103}Rh HMQC contour map obtained from a mixture of $[\text{Rh}(\text{H})(\text{PPh}_3)_4]$ (0.02 M), CySH (0.2 M) and Ph_3P (0.2 M) in 10% pyridine–toluene at -25°C . If the rhodium-103 nucleus is in an unsymmetric environment, it can also be detected easily by direct observation but in a symmetric environment this can be rather difficult.

There exist many papers on ^{103}Rh NMR. For example, small rhodium particles have been characterized by the ^{103}Rh NMR line broadening and chemical shift changes which have been interpreted in terms of both the electron-orbital (chemical) and electron-spin (Knight) shifts. Further, alkylrhodoximes, $[\text{Rh}(\text{Hdmg})_2\text{RL}]$, where Hdmg is the monoanion of dimethylglyoxime, L is H_2O , pyridine or PPh_3 and R is alkyl or an halomethyl, have been extensively studied by ^{103}Rh NMR spectroscopy. The ^{103}Rh shielding decreases in the order $\text{R} = \text{Et} >$

Me > Bu > Prⁱ > Buⁱ > *neo*-pent > Bu^t. In the case of [(P₂)Rh(hfacac)], where P = bidentate chelating phosphane and hfacac = hexafluoroacetylacetonate, correlations between solid state structures, ¹⁰³Rh NMR chemical shifts and catalytic activities (CO₂ hydrogenation) have been investigated. ¹⁰³Rh NMR chemical shift correlations have also been clarified for rhodium(III) complexes with cyanide and sulfur-donor ligands. A very interesting report describes a correlation between the rhodium-103 shielding in rhodium enamide complexes and the stereoselectivity of dihydrogen (H₂) addition to diastereomeric olefin complexes.

Palladium-105

Palladium belongs to the same group of elements as nickel and platinum. The only report dealing with ¹⁰⁵Pd NMR is on K₂[PdCl₆] for which the *LW*_{1/2} is 25 kHz.

Silver-107 and -109

From the NMR spectroscopic point of view, silver suffers from poor sensitivity owing to the low gyromagnetic ratio of both NMR-active isotopes. Further, long relaxation times make it necessary to incorporate long delays within the pulse sequence to avoid saturation effects during acquisition. Sensitivity enhancement by NOE effects is not possible owing to the negative γ value of both NMR-active silver nuclei. In spite of these unfavourable nuclear properties, there exist several papers on ¹⁰⁹Ag NMR. Although the natural abundance of the isotope-109 is less than that of 107, the larger γ value of 109 gives a better receptivity. As in the case of rhodium-103, direct observation of silver-109 is not useful and various polarization transfer techniques such as INEPT and HMQC are recommended. An example has been published by Berners-Price and co-workers where a retro-INEPT 2D ³¹P–{¹⁰⁹Ag} pulse sequence (published by Bodenhausen and Ruben for ¹⁵N–{¹H}) was utilized.

Remarkable progress in solid state ¹⁰⁹Ag NMR has taken place during the last few years. The first ¹⁰⁹Ag CP-MAS NMR spectrum was published by Merwin and Sebald in 1992. Some isotropic solid state ¹⁰⁹Ag NMR chemical shifts are included in Table 9 as well as a collection of characteristic solution-state data of silver-109.

Cadmium-11 and -113

Among the NMR-active isotopes included in this article the most exhaustively studied is certainly ¹¹³Cd. The reasons for this are quite obvious: *I* = 1/2 and a relatively good receptivity. Cadmium has also another NMR-active

Figure 2 DQF¹¹³Cd–¹¹³Cd COSY spectrum of MT-2. Reproduced with permission of the American Chemical Society from Frey MH, Wagner G, Vařak M, Sørensen OW, Neuhaus D, Wörgötter E, et al. (1985) Polypeptide-metal cluster connectivities in metallothionein 2 by novel ¹H–¹¹³Cd heteronuclear two-dimensional NMR experiments. *Journal of the American Chemical Society* 107: 6847–6851. Copyright 1985, American Chemical Society.

isotope (¹¹¹Cd) characterized with *I* = 1/2 but with a somewhat smaller receptivity than ¹¹³Cd. This is why ¹¹³Cd is preferred over ¹¹¹Cd. According to a review by Granger, the number of publications dealing with Cd NMR from 1980 to 1987 is ~160. Since then the number of papers on Cd NMR has continuously increased.

Figure 3 ^{113}Cd NMR spectra of the Cd(II) complexes of five different piperazine-pyridine ligands measured in ethanol at -50°C . The signal of the uncomplexed Cd^{2+} cation is marked by an asterisk. Reproduced with permission of VCH Verlagsgesellschaft from Ratilainen J, Airola K, Kolehmainen E, and Rissanen K (1997) Regioselective complexation of new multiple piperazine/pyridine ligands: Differentiation by ^{113}Cd -NMR spectroscopy. *Chemische Berichte/Recueil* 130: 1353-1359.

Therefore, including all the data available here is not possible. Nevertheless, owing to the significance of ^{113}Cd NMR in biological, inorganic, organic and organometallic chemistry extra attention is given to this NMR-active nucleus. At first sight it looks strange that

^{113}Cd NMR could possess any biological interest because cadmium is known to be a very toxic element for living organisms. However, the Cd^{2+} cation resembles closely the divalent cations of calcium and zinc which are involved in very many biological complexes. From an

NMR spectroscopic point of view these two cations are very impractical. Replacing calcium and zinc by cadmium in these complexes is often easy and opens new versatile NMR spectroscopic possibilities in this area of research. ^{113}Cd NMR studies in biochemistry and bioinorganic chemistry have been reported by Sadler and Viles on the binding sites of Cd^{2+} and Zn^{2+} in serum albumin and by Chung and co-workers on the binding of Cd^{2+} in soil fulvic acid.

The direct observation of ^{113}Cd is generally easy, although in some cases long relaxation times may cause prolonged acquisition times. This can be avoided by using a paramagnetic additive such as Gd^{3+} in the sample. If there exists a coupling between proton and cadmium, polarization transfer techniques such as HMQC are useful, as in the case of rhodium and silver. Owing to the relatively high natural abundance, homonuclear COSY can also be useful alternative in the case of ^{113}Cd . **Figure 2** shows the DQF (double quantum filtered) ^{113}Cd – ^{113}Cd COSY spectrum of cadmium metallothionein 2 (MT-2).

Although the observation of ^{113}Cd NMR spectral lines is easy and obtainable by a plethora of various measuring techniques, there is an obvious danger of oversimplification of the chemical shift data. This is because chemical exchange often occurs between different complexation or binding sites (including ligand and solvent) for cadmium and the observed Cd NMR line is a time average of the different chemical shifts from these different sites. Therefore it is recommended that ^{113}Cd NMR studies are carried out at low temperature to ‘freeze out’ these different species. **Figure 3** shows the ^{113}Cd NMR spectra of five different Cd(II) complexes of multiple piperazine–pyridine ligands measured in ethanol at -50°C .

Cd^{2+} cations can form salts and complexes with numerous anions and molecules that bear free electron pairs. For example, in supercooled water at -80°C five different CdI_n^{2-n} ($n=0-4$) species are observed with the chemical shifts -86 , $+20$, $+43$, $+122$ and $+101$ ppm, respectively. Generally, ^{113}Cd NMR chemical shifts are referenced to the signal of 0.1 M aqueous $\text{Cd}(\text{ClO}_4)_2$. For low-temperature measurements this reference is not suitable and 0.1 M $\text{Cd}(\text{ClO}_4)_2$ in ethanol can be used. In **Table 10** are collected some characteristic ^{113}Cd NMR chemical shifts. In addition to the monometal compounds and complexes, cadmium can form clusters with several cadmium and/or zinc atoms which also are characterized by ^{113}Cd NMR.

As noted before, the isotropic ^{113}Cd NMR chemical shift determined in solution is influenced by exchange processes, temperature, concentration and solvent effects which may limit the interpretation of the structural data. In the solid state, complete information concerning the shielding tensor can be obtained without the difficulties

mentioned above. From single-crystal NMR experiments the orientation of the principal elements of the shielding tensor with respect of the coordinate system based on the molecule are obtained. Further, this knowledge provides information on the coordination of cadmium, for example in the active site of metalloproteins such as parvalbumin and concanavalin A. There exist many solid state NMR studies on cadmium complexes with ligands that contain nitrogen, oxygen and sulfur donor groups. A novel application of solid state ^{113}Cd NMR is an investigation on host-guest systems. In these studies ^{113}Cd NMR has been used to differentiate the possible coordination environments.

Summary

In an article with a limited length and depth of coverage like this, dealing with 10 elements and 14 NMR-active nuclei, it is impossible to discuss all the important NMR parameters. Therefore, most attention has been paid to

NMR chemical shifts while spin–spin coupling constants and relaxation times are only mentioned in the contexts where they should be taken into account to obtain useful NMR results. However, as well as direct NMR detection, one should remember, for example, the usefulness of the (inverse) two-dimensional pulse sequences and the MAS technique to utilize homo- and heteronuclear spin–spin coupling constants for polarization transfer between nuclei to enhance the sensitivity of the measurement. These approaches have increased the number of heteronuclear NMR applications dramatically and should play an important role in future studies.

Y	number of reaction products
$Y(Z, E)$	yield of interaction
z	charge
σ	cross-section
ε	detector efficiency
Ω	solid angle

The interactions between medium energy (1–5 MeV) atomic ions and the atoms of a sample produce a wide variety of reaction products; electromagnetic radiation from the electron shells or gamma rays from the nucleus, scattered particles from the primary beam which may be modified in direction and energy, or particles of a different species emitted from the nucleus. Any of these may be analysed spectroscopically using suitable detectors to provide information about the elemental and in some cases isotopic composition of the sample.

Analysis using MeV Ions

Interactions of MeV Ions in Matter

MeV ions interact with matter through collisions with the electrons and nuclei of the atoms of the material. Ion–electron collisions give rise to reactions associated with the electron shells of atoms (photon emission, Auger electrons, conduction electrons or holes, secondary electron emission) and nuclear collisions give rise to reactions involving the nucleus (nuclear scattering, atomic displacement, sputtering, nuclear reactions resulting in gamma ray or particle emission). The products of these reactions may be detected and used for analytical purposes.

In nuclear scattering theory, the relative probability of a reaction taking place is expressed as a cross-section, σ . Each atom or nucleus is represented by a disk of area σ , and if a beam particle passes through this disk, a reaction takes place resulting in the detection of a particle or photon in a detector with 1 steradian (sr) solid angle. Thus high yield reactions have a high cross-section. Values of cross-section are of the order of 10^{-24} cm^2 , and this quantity is called 1 barn. Reaction cross-sections are usually quoted as barn sr^{-1} . The yield of a particular reaction may be calculated using the expression

$$Y = \Omega \sigma N n_T \quad [1]$$

where Y is the number of reaction products (photons, particles) detected in a detector of solid angle Ω sr when a sample containing n_T target atoms per square centimetre is bombarded with N projectile ions. Here, the cross-section, σ , is assumed to be in square centimetres.

Cross-sections for ion–atom reactions vary over a wide range depending on the specific reaction, the ion and atom (or nuclear) species, the ion energy and the angle of detection. Clearly for analytical purposes, high cross-section reactions are preferable, but this also depends on the relative intensity of any competing reactions which produce a background signal. In many cases, ion beam analysis (IBA) reactions are free from background so that even low cross-section reactions may be used for analysis.

PIXE (Proton Induced X-Ray Emission)

In PIXE, the basic interaction between the beam and the sample which gives rise to the emission of characteristic X-rays is analogous to the processes involved in electron induced X-ray emission (EDX, or electron probe microanalysis, EPMA). In each case, the charged particle in the beam creates inner electron shell vacancies in the sample atoms, leaving them in an excited state which decays by electron transitions from higher shells, each of which causes the emission of an X-ray quantum whose energy is determined by the atomic number of the atom. This can be detected using either a wavelength dispersive crystal spectrometer (WDX) or an energy dispersive lithium drifted silicon detector (Si–Li) (EDX). The use of WDX detectors is not common in PIXE.

Because of the use of Si-Li detectors, EDX and PIXE share many characteristics, especially the advantage of rapid multielemental analysis, but the use of MeV protons as the incident particle gives one crucial advantage over the technologically simpler use of keV electrons in an electron microscope, and that is in reducing the background of broad spectrum non-characteristic X-rays. In EDX, the major source of background is created by the scattering and deceleration of the electrons of the primary beam as they collide with the electrons in the sample. Each collision gives rise to a large change in momentum of the primary electron and causes the emission of broad spectrum 'Bremsstrahlung' radiation which has a maximum energy equal to the beam energy. Bremsstrahlung is the major source of background in EDX and is a fundamental limitation to the minimum detectable limit (MDL).

In contrast, MeV ions lose negligible momentum in each collision with an electron, which means that the primary Bremsstrahlung is effectively absent, permitting the detection of weak characteristic X-ray lines and giving a reduction in MDL of 100 to 1000 times over EDX. PIXE is not totally free from background; the electrons created during the initial ionization generate a background at low energies (secondary electron Bremsstrahlung), which limits the MDL for elements in the range Na to Fe (depending on the primary beam energy), but a substantial improvement (two to three orders of magnitude) over EDX is achieved. **Figure 1** presents a comparison of EDX and PIXE on the same sample of brain tissue showing the improvement in sensitivity resulting from the lack of Bremsstrahlung.

Like EDX, the lightest element that may be detected is determined by the response of the detector to low

Figure 1 Energy dispersed X-ray spectra from the same sample excited by 20 keV electrons (top) and 2.5 MeV protons (bottom). The enhancement of the detection limit for the trace elements caused by the absence of primary Bremsstrahlung in the PIXE spectrum can be seen clearly. Reproduced with permission of Wiley from Johansson SAE, Campbell JL, and Malmqvist KG (1995) *Particle-Induced X-ray Emission Spectrometry*. New York: Wiley.

energy X-rays, and with conventional beryllium window detectors, the lightest element that can be routinely detected is sodium. PIXE has a high cross-section (typically 10–1000 barn sr^{-1}) which makes it very well suited for use with microprobe systems.

Each element has a characteristic spectrum of X-ray emission lines with energies depending on the atomic number. These lines are categorized into groups depending on which electron shell was ionized in the collision. For example, the K series consists of lines denoted as $K_{\alpha 1}$, $K_{\alpha 2}$, ... $K_{\beta 1}$, $K_{\beta 2}$... resulting from transitions between the L subshells and the K subshells. The K_{α} and the K_{β} sublines have energies which are close in value, so that with a detector of moderate energy resolution such as Si–Li, only two peaks are observed. The L series, resulting from transitions between the M subshells and the L shells, is more complex with three main groups (L_{α} , L_{β} , L_{γ}) and several less intense peaks. In heavy elements (above Ba), the M series (N shell to M shell) may also be observed, but the M lines are not often used for quantification. **Table 1** shows the energy of the most intense K, L and M lines from selected elements, with those detectable using a

typical Si–Li detector. The table shows that by using both the K series and the L series all elements heavier than Na may be detected using PIXE. It also highlights the possibility of interference between the series of different elements (e.g. As K_{α} has almost the same energy as Pb L_{α}). When all the sublines of each series of each element in the sample are taken into consideration, the probability of overlaps is very high, and spectrum processing software must be capable of handling this.

Figure 2 shows the PIXE spectrum from a single ambient aerosol particle, showing the major and trace elements detected.

Absorbers

One characteristic of PIXE analysis is the wide dynamic range of the significant peaks. Intense peaks from major elements in the sample may contain millions of counts, while in the low background region of the spectrum, significant peaks containing less than 10 counts may be observed. For this reason, PIXE spectra are normally presented with a logarithmic vertical scale. Another consequence of this is that spurious responses from intense peaks in the detector can have a drastic effect in swamping the small peaks from trace elements. For this reason, the careful use of X-ray absorbers (filters) is crucial to obtaining the best performance with PIXE. For example, when analysing bone, an absorber (typically of Al or a polymer foil) may be fitted to reduce the intensity of the Ca peak to zero or a few parts per thousand to minimize the background and spurious peaks due to the intense flux of Ca X-rays. This is crucial in improving the detection limits for the metals. Fitting an absorber means that X-ray lines of lower energy than the line being removed are lost completely, and it is becoming more common now to use two detectors simultaneously, one unfiltered for major elements and one with a suitable filter for the trace elements.

The art of PIXE analysis lies in the selection of the optimum filter.

Table 1 Energies (in keV) of the K_{α} , L_{α} , and M_{α} lines of selected elements. Energies in italic face may be detected using a typical Si–Li detector

Element	K_{α} energy	L_{α} energy	M_{α} energy
Li	0.052		
O	0.523		
Na	1.041		
Si	1.740		
Ca	3.691	0.341	
Fe	6.403	0.704	
As	10.534	1.282

Ag	22.162	2.984	0.568
Ba	32.191	4.467	0.972
W	59.310	8.396	1.774
Pb	74.957	10.549	2.342
Pu	103.653	14.297	3.350

Figure 2 Proton-induced X-ray spectrum from a single ambient aerosol particle of 2 μm diameter. The spectrum was collected in 5 min using a beam of 3 MeV protons focused to a diameter of 1 μm at a current of 100 pA.

Quantification of PIXE Spectra

Figure 2 shows that a PIXE spectrum consists of peaks which are approximately Gaussian sitting on top of a continuous background. The background-subtracted area of each peak is proportional to the concentration of the associated element, and a number of software packages are now available to perform the processing required to extract the areas and convert these to true concentrations.

For a sample consisting of a thin film (so that proton energy loss and X-ray absorption can be neglected), the yield of characteristic X-ray photons of energy E_x from element Z induced by particles of energy E is given by

$$N = C_z Q \Omega \varepsilon(E_x) Y(Z, E) \quad [2]$$

where N is the total number of photons detected using a detector of solid angle Ω , Q is the total beam charge, C_z is the concentration of the element and $\varepsilon(E_x)$ is the dependence of detector efficiency on X-ray energy. $Y(Z, E)$ is the yield of the interaction expressed as counts per unit of concentration per unit of charge per unit of solid angle. This, in turn, is derived from the ionization cross-section (the probability of creating a vacancy) and the fluorescence yield (the number of photons emitted in each X-ray line for each vacancy).

In more realistic thick samples, the calculation must also take account of the energy loss of the particle as it penetrates the sample and also the absorption of the X-rays as they emerge from the sample. To do this, a knowledge of the bulk composition of the sample is required (together with any variation with depth) and both the stopping power of the ion in the matrix and the X-ray attenuation coefficient must be known. The calculation then involves a numerical integration of the total X-ray yield from each sublayer of the sample.

All of the physical parameters involved in this calculation (ionization cross-section, fluorescence yield, stopping power, X-ray attenuation and detector efficiency) have been measured and parameterized with sufficient accuracy that quantitative PIXE analysis may be carried out without routine reference to standards once the fixed system parameters have been determined. A small number of computer programs have been developed to carry out PIXE spectrum processing, and special mention must be made of GUPIX, developed at the University of Guelph, Ontario, which embodies the most detailed physical model of the PIXE process and also offers the capability to iterate the sample matrix composition (including user-defined 'invisible' elements such as oxygen) until the matrix composition matches the values obtained from the peak areas.

Accuracy and Detection Limit of PIXE

The major sources of error in a PIXE measurement and the above calculation are as follows:

- (1) *Inaccuracies in the basic assumptions about the target.* The calculation assumes that the sample is a flat homogeneous slab of the given composition. Any departure from this model (surface roughness, compositional variation with depth, etc.) will introduce an error in the calculated relative intensity of the X-ray lines.
- (2) *Inaccuracies in the physics database.* These may contribute errors to the relative X-ray intensities, but it is believed that the database is of sufficient accuracy that these are relatively insignificant compared with other sources of error.
- (3) *Numerical and statistical errors in processing the spectrum.* The quality of the final fit depends on the fitting procedure and the amount of detail in the mathematical model. The precision of each peak determination also depends on the quality of the statistics in the experimental spectrum. Peaks with few counts will not be fitted so well as intense peaks.
- (4) *Limitations in the model used for the detector response function and absorber transmission.* The response of the detector varies with X-ray energy (and also depends on any absorbers used). This can be simulated using a simple physical model of the detector and parameterized expressions for X-ray absorption coefficient. However, for the highest accuracy it is necessary to analyse standard samples and derive a correction factor for each X-ray line of interest.
- (5) *Inaccuracies in determining the charge and detector solid angle.* These affect the absolute accuracy but not the relative concentrations. For this reason it is more accurate to use PIXE to determine element ratios rather than absolute values. The charge is difficult to measure accurately since the beam currents involved are generally quite small and also large numbers of secondary electrons are created in the beam impact on the sample, which, if they are not returned to the sample, will give an error in the measurement. Beam current normalization is often carried out by using PIXE simultaneously with another technique (e.g. Rutherford backscattering (RBS), which also offers the possibility of determining the sample matrix independently).

When all these sources of error have been addressed, it should be possible to achieve a relative accuracy of the order of 5–10% and an absolute accuracy of 10–20%.

The detection limit depends on the height of the peak relative to the background (which now can mean both the continuum background and also any overlapping X-ray lines or detector artefacts). The detection limit is conventionally defined as 3 times the square root of the area of the background within one standard deviation of the peak centre (converted to concentration using the

same factor as for the peak). This depends on all the parameters of the experiment, and **Figure 3** shows the theoretical detection limits for trace elements in a carbon matrix. This indicates that values of the order of 0.1–1 ppm may be expected under optimum conditions.

RBS (Rutherford Backscattering)

Particle backscattering spectrometry, also known as Rutherford backscattering or RBS, involves measuring the recoil energy of backscattered particles from the primary beam to obtain analytical information. Ions recoiling from direct elastic collisions with the nuclei of atoms in the sample lose energy according to the mass of the target atom; recoils from heavy nuclei have a higher energy than recoils from light nuclei. If the target atom is not at the surface, energy is also lost during the passage through the sample to and from the reaction site (**Figure 4**), so measuring the energy distribution of

Figure 3 Minimum detectable limit of trace elements in a carbon matrix as a function of atomic number and proton energy. The calculation assumes a beam charge of 1 μC and curves are presented for K and L lines. Reproduced with permission of Wiley from Johansson SAE, Campbell JL, and Malmqvist KG (1995) *Particle-Induced X-ray Emission Spectrometry*. New York: Wiley.

Figure 4 Typical geometry for Rutherford backscattering. The incident particle loses energy ΔE_1 going through the sample to the scattering site, loses energy ΔE (determined by the Rutherford formula) in the collision and loses energy ΔE_2 on the recoil path to the detector.

recoiling atoms gives information on the major element composition and depth distribution in the sample. This technique is loosely complementary to PIXE in that the greatest mass resolution occurs for the light elements which are invisible using PIXE. The cross-sections are lower than for PIXE (typically 0.1–10 barn sr^{-1}); therefore the minimum detectable limit is not so low as for PIXE (typically 0.1%), but RBS can be used for determining major element composition and depth profiles. In certain favourable cases (e.g. heavy inclusions embedded in a light matrix) RBS can be used to carry out non-destructive three-dimensional mapping. Used simultaneously with PIXE, RBS provides, in principle, analysis of all elements above He in the periodic table.

Interpreting RBS Spectra

The classical treatment of the scattering of two charged particles yields the following expressions for the recoil energy and for the cross-section:

$$E = E_0 \frac{m_1^2}{(m_1 + m_2)^2} \left[\cos\theta + \left(\frac{m_2^2}{m_1^2} - \sin^2\theta \right)^{\frac{1}{2}} \right]^2 \quad [3]$$

$$\frac{d\sigma}{d\Omega} \approx 1.296 \left(\frac{zZ}{E_0} \right)^2 \left[\sin^{-4}\left(\frac{\theta}{2}\right) - 2\left(\frac{m_1}{m_2}\right) + \dots \right] \quad [4]$$

where E is the recoil energy of a particle of mass m_1 , charge z and initial energy E_0 scattering through a total angle θ from a stationary nucleus of mass m_2 and charge Z . The form of these expressions is shown in **Figure 5** for 3 MeV protons and alpha particles recoiling off nuclei up to mass 100. These curves show that the best mass resolution (change in recoil energy with mass) occurs for low masses. At high masses, the difference in recoil energy is too small to identify the mass of the scattering

Figure 5 Recoil energy (left axis) and scattering cross-section (right axis) for 3 MeV protons (solid line) and alpha particles (dashed line) backscattering from nuclei of different masses. Scattering angle, θ , 150° (i.e. beam to detector angle 30°).

nucleus uniquely. The curves also show that the cross-section increases with mass. Alpha particles give both a higher cross-section and a better mass resolution, and these are normally used for RBS applications.

Because of the interplay of mass and depth information in RBS spectra, interpreting the data is not so straightforward as, for example, in PIXE spectroscopy where each peak is uniquely associated with a particular element. At present, RBS spectrum interpretation relies on simulating the spectrum from a proposed model of the

sample using a suitable computer program, for example the commonly used program, RUMP. The parameters of the model can then be refined, either manually or using fitting routines, until a good match is obtained to the experimental data. Thus, some insight into the physics of the situation is required in order to decide on a suitable starting point for the modelling procedure. Some of the points to be considered are presented in **Figure 6a–e** which show simulated RBS spectra. In **Figure 6a** recoils from a very thin SiO_2 film give two narrow peaks, one at

Figure 6 Simulated RBS spectra using 3 MeV protons scattered at an angle of 150° for the following samples: (a) $0.1\ \mu\text{m}$ film of SiO_2 , (b) $5\ \mu\text{m}$ film of SiO_2 , (c) Thick sample of SiO_2 , (d) $0.01\ \mu\text{m}$ Cu film on SiO_2 , (e) $2.5\ \mu\text{m}$ Cu film on SiO_2 . Simulations (a)–(e) carried out using the Rutherford cross-section (eqn [3]). (f) Simulation of $2.5\ \mu\text{m}$ Cu film on SiO_2 (case (e)) using true light element cross-sections for Si and O.

higher energy from Si and one at lower energy from O. The relative areas of the peaks are proportional to the ratio of Si to O. In **Figure 6b** a thicker film of SiO_2 gives two broader peaks, as recoils from deeper inside the sample occur at lower energies. The energy width of the peaks increases with increasing sample thickness. In the case of an infinitely thick sample, **Figure 6c**, the responses from Si and O merge and instead of seeing peaks, the presence of the two elements is seen as steps or edges corresponding to the recoil energy of that element at the surface. When a thin Cu film is added to the surface of the SiO_2 , this is seen as a sharp peak at higher energy (**Figure 6d**), and if the Cu layer is made thicker (**Figure 6e**), the Cu peak becomes broader, but also the Si and O edges are shifted to lower energy because of the energy loss in the Cu film.

The use of RBS with protons on light nuclei is complicated by nuclear reactions (see below) and the cross-section may be much higher (or lower) depending on the energy and the scattering angle. This is illustrated in **Figure 6f**, which shows the same simulation as in **Figure 6e**, but now using true cross-sections rather than the theoretical Rutherford formula. It can be seen that the yield for O is significantly higher than the Rutherford case due to nuclear reactions, and this can be exploited to increase the sensitivity to O. The dip in the spectrum observed at about 1600 keV is due to a nuclear reaction in ^{16}O which reduces the cross-section over a limited energy range.

In spite of the relative complexity of interpreting the spectra, RBS with alpha particles is widely used for materials analysis for characterizing thin film structures or depth profiles of impurities or dopants. RBS with protons can be used simultaneously with PIXE to help to determine the bulk matrix composition and also the incident beam charge.

Nuclear Reaction Analysis (NRA)

If the incident ion penetrates the repulsive electrostatic field surrounding the nucleus of a target atom, it is possible for nuclear reactions to take place involving the weak and strong nucleonic forces. This can result in the formation of an excited unstable compound nucleus which may decay by the emission of particles or gamma rays to give a final nucleus which may be different from the original. Nuclear reactions in general have a much lower cross-section than atomic reactions such as PIXE (typically $10\text{--}100\text{ mb sr}^{-1}$), but they often have resonant behaviour, so that provided the conditions are carefully chosen, NRA may give a useful yield and unique information. The cross-section and the types of reactions observed are strongly dependent on the isotope of the target atom and the beam energy and do not vary in a systematic way with atomic number, as do the yields and

X-ray energies in PIXE. Nuclear reactions are often described using the notation $A(a,b)B$, where A and B are the initial and final states of the target nucleus, a is the projectile ion and b is the emerging reaction product (particle or gamma rays).

Nuclear reactions tend to be most important for light nuclei, as the Coulomb repulsion is less for nuclei with low Z. There are three types of nuclear reaction which are of interest for analytical purposes and these are described below. In general, because of the rapid and irregular variation of cross-section with energy, NRA techniques are difficult to quantify and in the majority of cases, quantitative data is obtained by comparison with known standards.

Resonant Elastic Scattering

At certain energies, the yield of RBS analysis may be strongly enhanced (or reduced) by interactions with the target nucleus. One example of this is resonant scattering of protons from ^{12}C , i.e. $^{12}\text{C}(p,p)^{12}\text{C}$. At an energy of $1.76 \pm 0.1\text{ MeV}$, the cross-section for backscattered protons from ^{12}C increases by a factor of 60 relative to the classical Rutherford formula and this can be exploited to improve the sensitivity for carbon. This is shown in the simulations of **Figure 7**, for a 10 nm thick layer of carbon on a copper substrate.

Nuclear Reactions Resulting in Gamma Ray Emission

Most nuclear reactions result in the emission of gamma rays of a well-defined characteristic energy and these can be energy-analysed using a suitable detector and used for analysis. This technique is sometimes referred to as particle-induced gamma emission or PIGE. PIGE is useful for fluorine determination, for example, since the reaction $^{19}\text{F}(p,\alpha\gamma)^{16}\text{O}$ has a particularly high yield, though many other light elements up to Al can also be detected with a reasonable detection limit. **Figure 8** shows the gamma ray spectrum of a tourmaline, a mineral rich in light elements such as F, Li and B, bombarded

Figure 7 Simulated RBS spectra of a 10 nm layer of C on a Cu substrate using protons of 3 MeV and 1.76 MeV, which correspond to the (p,p) resonance in ^{12}C .

Figure 8 Gamma ray spectrum from a tourmaline bombarded with 3 MeV protons. Gamma ray lines corresponding to F, Li, B, Na and Al are marked. The unmarked lines are created by background sources within the fabric of the laboratory.

with 3 MeV protons showing the characteristic lines from the light elements in the sample.

Nuclear Reactions Resulting in Particle Emission

Some nuclear reactions result in the emission of a particle (proton or alpha) with an energy higher than the primary beam energy so that they can be detected unambiguously in the detector used for RBS analysis. Relatively few reactions are useful for analytical purposes. One example is ${}^7\text{Li}(\text{p},\alpha){}^4\text{He}$, which occurs when Li is bombarded with 2–3 MeV protons. Two alpha particles are emitted which have energies of 7–8 MeV and can be detected with no interference from the spectrum of backscattered protons.

Equipment for Ion Beam Analysis

Accelerators

The major component of any nuclear microbeam facility is the particle accelerator. This must generate ions of the species and energy required to carry out the analysis (protons and alpha particles with energies of a few MeV), but the requirement of operating with a focusing system may also impose additional requirements on the energy spread and brightness of the beam.

The accelerators most suitable for IBA are the electrostatic type, in which a static voltage equal to the beam energy required is generated, and the particles are accelerated in a single step (or two steps if the ‘tandem’ principle is used). The voltage may be generated either by an electrostatic system such as the popular ‘van de Graaff’ system, or by a voltage multiplier stack, in which an alternating voltage is rectified in such a way as to generate a DC voltage many times greater than the

amplitude of the applied voltage. **Figure 9** shows schematically the principle of electrostatic accelerators.

Historically a nuclear accelerator formed part of a major facility and many IBA installations still compete for beamtime at a nuclear physics accelerator institute. In contrast, modern small accelerators represent a relatively modest investment in capital and support costs and increasingly now, new small accelerators are being purchased specifically for analytical applications. It is notable, for example, that the Louvre Museum in Paris now houses a modern accelerator facility (Accelérateur Grand Louvre pour Analyses Élémentaire – AGLAE) dedicated to the analysis of art objects and archaeological samples.

Detectors

The majority of detectors used in IBA are based on the reverse biased semiconductor junction. Ionizing radiation creates electron–hole pairs in the depletion region of the junction which drift under the applied electric field to the electrodes where they create a voltage pulse which is amplified. The material and dimensions of the detector depend on the radiation to be detected, and must be chosen so that the incident photon or particle has a high probability of interacting with an atom in the depletion region (**Table 2**). In order to reduce the noise due to thermal electrons, photon (X-ray and gamma) detectors must be operated with the detector crystal and preamplifier at a low temperature (usually with liquid nitrogen cooling, but newer semiconductor materials such as cadmium zinc telluride can give good performance with Peltier junction cooling devices). For particle detectors, other sources of noise dominate and these can be operated at room temperature.

Figure 9 Schematic diagram of (a) single ended accelerator and (b) tandem accelerator. The terminal voltage may be generated either by a moving belt or chain (the van de Graaff or Pelletron principle) or by rectifying a high frequency alternating voltage (the Tandatron). In the single-ended accelerator a positive ion source is mounted in the terminal and the beam energy is equal to the terminal voltage. In the tandem accelerator an external *negative* ion source injects ions into the accelerator where they are accelerated towards the positive terminal. In the terminal they pass through a region of low pressure gas (the stripper) where collisions with the gas molecules remove some, or all, of the electrons. The resulting positive ion is further accelerated. The final energy is given by $V(1 + q)$ where V is the terminal voltage and q is the charge state after stripping. The accelerator assembly is normally enclosed in a pressure vessel containing several atmospheres of an insulating gas such as SF_6 to avoid the possibility of electrical discharges.

Applications of Nonspatially Resolved IBA

PIXE and RBS are the major spectroscopic techniques used for materials analysis because of their high yield and

relative ease of quantification. In many cases, however, the use of nonspatially resolved, or 'broad beam' PIXE has been displaced to some extent by inductively coupled plasma mass spectrometry (ICPMS), which offers the

Table 2 Properties of semiconductor detectors used for spectroscopic analysis of charged particles, X-rays and gamma rays

Name ('common name')	Silicon surface barrier detector (surface barrier, SSB)	Lithium drifted silicon (Si-Li)	High purity germanium (HpGe)
Radiation	MeV charged particles	X-rays	Gamma rays
Physical form	Thin disk of Si typically 10–30 mm diameter with depletion layer formed beneath an insulating 'barrier' on the surface	Single crystal Si disk typically 10 mm diameter, 4 mm thick. Li diffused into Si to compensate defects and impurities to ensure efficient charge collection	High purity single crystal Ge cylinder typically 20 mm diameter, 80 mm long
Must be cooled?	No	Yes	Yes
Depletion layer thickness	Typically 100 μm	~ 4 mm	~ 80 mm
Entrance window	None	Varies: typically 10 μm Be. Also ultra-thin polymer windows to extend lower energy range	Thin (~ 1 mm) Al
Energy range	~ 10 keV to MeV. Upper limit depends on depletion depth	~ 1 –50 keV. Lower limit depends on window; upper limit depends on crystal thickness	~ 30 keV–10 MeV. Lower limit depends on window and electronic noise; upper limit depends on crystal dimensions

same advantages of rapid multielemental analysis with the additional advantage of very low detection limits and greater accessibility. However, PIXE still has advantages of speed and ease of sample preparation and is used routinely in a number of applications, especially ambient aerosol filter analysis. Broad beam RBS still has a wide application in characterizing thin films and diffusion profiles of impurities in solids, for example in measuring thickness of metallization layers on silicon or depth profiles following implantation of dopants into semiconductors. The technique may also be combined with channelling, in which the variation of yield as the beam is aligned with one of the major axes of a single crystal sample can be used to obtain information on lattice quality and the localization within the lattice of impurity atoms. A full discussion of channelling is beyond the scope of this article.

PIXE (and to a certain extent RBS) is now more commonly used in the spatially resolved mode. This is because their high yield contributes to the attainment of high spatial resolution.

Introduction

The use of pressure as an experimental variable in NMR studies of chemical and biochemical systems leads to added complexity in instrumentation but the unique information gained from the combination of high pressure and NMR techniques justifies fully its use. There are several fundamental reasons for carrying out NMR experiments at high pressures.

First, to separate the effects of density and temperature on various dynamic processes, one has to perform the measurements as a function of pressure. Second, for liquids the use of pressure enables one to extend the measurement range well above the normal boiling point and thus to study supercritical fluids. Third, as non-covalent interactions play a primary role in stabilization of biochemical systems, the use of pressure allows one to change, in a controlled way, the intermolecular interactions without the major perturbations produced by changes in temperature and/or chemical composition. Fourth, pressure affects chemical equilibria and reaction rates. The following standard equations define the

reaction volume, ΔV and the activation volume, $\Delta V^\ddagger$:

$$\Delta V = - \left[\frac{RT \partial \ln K}{\partial P} \right]_T, \quad \Delta V^\ddagger = - \left[\frac{RT \partial \ln k}{\partial P} \right]_T$$

where K is the equilibrium constant, and k is the reaction rate. With the knowledge of $\Delta V^\ddagger$ values one can draw conclusions about the nature of reaction and its mechanism. Fifth, the phase behaviour and dynamics of molecular solids and model membranes can be explored more completely by carrying out high pressure experiments. Sixth, the combination of advanced 2D and 3D NMR techniques with high pressure capability represents a powerful new experimental tool in studies of protein folding.

The usual range of pressures used to investigate chemical and biochemical systems is from 0.1 MPa to 1 GPa (0.1 MPa = 1 bar; 1 GPa = 10 kbar); such pressures only change intermolecular distances and affect conformations but do not change covalent bond distances or bond angles.

Pressure Effects on NMR Spectra

This heading is related to the fact that the effects of pressure and/or density on chemical shifts and spin–spin coupling in molecular systems are relatively small and difficult to interpret. In contrast, most of the high pressure NMR studies of chemical or biochemical systems deal with pressure or density effects on dynamical behaviour of the readily compressible gases, molecular liquids and aqueous solution of biomolecules. Increasing pressure changes both the density and shear viscosity of the liquids which in turn changes the relaxation times and chemical exchange. The majority of NMR studies deal with liquids of low viscosity for which $T_1 = T_2$ and the condition of extreme motional narrowing applies. In the case of rotational motions of a spherical top molecule the following expression can be used to calculate the rotational correlation time, τ_R , from proton relaxation times

$$\frac{1}{T_1} = \frac{3}{2} \hbar^2 \gamma^4 \sum_{i,j} r_{ij}^{-6} \tau_R$$

where γ is the gyromagnetic ratio for hydrogen and r_{ij} is the distance between protons. However, for

proton-containing molecules one has to separate the intramolecular and intermolecular contributions to the observed proton relaxation times. In the case of nuclei with spin $I > \frac{1}{2}$ the relaxation studies provide direct information about rotational motions because the electric quadrupole interactions provide the dominant relaxation mechanisms. For nuclei with spin $I = 1$ (e.g. ^2H , ^{14}N), the relaxation rate due to the quadrupolar interaction is given by the well-known expression

$$\frac{1}{T_1} = \frac{3}{8} (1 + \chi^2/3) (e^2 q Q / \hbar)^2 \tau_R$$

where χ is the asymmetry parameter, $e^2 q Q / \hbar$ is 2π times the quadrupole coupling constant in hertz, and τ_R is the rotational correlation time.

It is well established that the rotational correlation time, τ_R , for the isotropic rotation of a spherical top molecule can be expressed in terms of the macroscopic viscosity, η , using the Debye equation

$$\tau_R = \frac{4\pi a^2 \eta}{3k_B T}$$

where η is the viscosity, a is the radius of the molecule and the other symbols have their usual meaning.

In the case of the intermolecular contribution to relaxation times of proton-containing molecules and for the effect of pressure on self-diffusion one can use the Stokes–Einstein expression, which relates the shear viscosity, η , to the self-diffusion coefficient D :

$$D = \frac{k_B T}{6\pi a \eta}$$

where all symbols have their usual meaning.

For non-hydrogen bonded liquids the increase of pressure slows down both rotational and translational motions with the result that for low viscosity liquids one shortens the spin–lattice relaxation times and decreases the diffusion.

The slowing down of exchange owing to increased pressure in chemically exchanging systems also leads to changes in the NMR spectra. As discussed elsewhere in this encyclopedia, high resolution NMR spectroscopy is widely used to study chemical exchange processes. As an example of the effect of pressure on chemical exchange **Figure 1** shows the pressure dependence of hindered rotation about the C–N amide bond in *N,N*-dimethyl-trichloracetamide (DMTCA). From the observed line shapes it is straightforward to calculate the observed reaction rate and from its pressure dependence one can calculate the volume of activation $\Delta V^\ddagger$. In the case of DMTCA the experimental rotation rate, k , decreases with increasing pressure and the correlation of the rates with measured viscosity (shear viscosity, η) shows that

Figure 1 Pressure effects on the line shape of the N-methyl proton NMR spectrum of DMTCA in pentane at 282.3 K. The dotted lines denote the experimental line shapes, and the full lines denote the calculated line shapes.

the hindered rotation in DMTCA falls in the strongly coupled diffusive regime.

There is yet another important origin of observed pressure changes in the NMR spectra of biomolecules in aqueous solutions. NMR studies of protein denaturation using temperature or chemical means are well established but pressure also leads to reversible denaturation as discussed in more detail in the section on applications. In the case of model membranes the use of pressure leads to very rich barotropic behaviour and high pressure NMR techniques can establish pressure–temperature phase diagrams for the membrane system studied.

In addition to gases and liquids the NMR spectra of molecular solids exhibit sensitivity to pressure. The relaxation behaviour is changed and, in addition, pressure also leads to changes in phase-transition temperatures.

The effect of pressure on the phase-transition temperature can be evaluated using the Clausius–Clapeyron

equation:

$$\frac{dT}{dP} = T \left(\frac{\Delta V}{\Delta H} \right)$$

where T is the transition temperature, P is the pressure, ΔV is the molar volume change and ΔH is the change in molar enthalpy.

High Pressure NMR Instrumentation

Since high resolution NMR spectroscopy represents a spectroscopic technique of major importance for chemistry and biochemistry the overview of high pressure NMR instrumentation focuses on high resolution, high pressure NMR techniques.

Thanks to advances in superconducting magnet technology one can achieve a high homogeneity of the magnetic field over the sample volume even without sample spinning and, therefore, it is possible to construct high resolution NMR probes for work at high pressures. The high resolution, high pressure NMR equipment consists of three main parts: (a) pressure generating and pressure measuring systems; (b) nonmagnetic high pressure vessel; and (c) an NMR probe that includes a sample cell. All components necessary for building a high pressure setup, such as hand pumps, high pressure tubing, and valve intensifiers, are currently available from commercial sources. **Figure 2** shows a schematic drawing of a high pressure generating system capable of producing a hydrostatic pressure up to 1 GPa. In addition to high

pressure NMR instrumentation based on a high pressure vessel made from non-magnetic metallic alloy, one can also obtain high resolution NMR spectra using glass capillaries or special sample cells made from sapphire. **Table 1**, which gives characteristic performance features of high pressure NMR probes, also includes information on the diamond anvil cell (DAV) which is suitable for broad-line work up to pressures of 8 GPa. However, the extremely small sample size makes DAV probes difficult to operate and relatively insensitive.

A schematic drawing of a high pressure NMR vessel, and a sample cell used for high resolution NMR experiments at pressures up to 950 MPa, is shown in **Figure 3**. It is important to note that even at pressures of 1 GPa and sample diameter of 8 mm one can achieve a resolution of 3×10^{-9} . The natural abundance ^{13}C NMR spectrum of 2-ethylhexylcyclohexanecarboxylate recorded at 80 °C and 500 MPa as shown in **Figure 4** serves as an illustrative example of the high quality NMR spectra which can be routinely obtained at high pressures.

Applications of High Pressure NMR Spectroscopy

Dynamic Structure of Liquids

Theoretical and experimental evidence indicate that many physical properties of liquids may be determined, to a large extent, by the size and shape of the constituent atoms or molecules. Owing to the close packing of molecules in liquids, even a small change in density can

Figure 2 Schematic diagram of the high pressure generating equipment.

Table 1 Characteristic performance features of high pressure NMR probes

Probe type	Pressure range (MPa)	Temperature range (K)	Sample diameter (mm)	Resolution ($\times 10^{-9}$)	^1H Frequency (MHz)
Capillary cell	0.1–250	^a	1–1.5	3	^a
Sapphire cell	0.1–100	^a	3.4	1.5	^a
HP vessel	0.1–950	253–373	8	3	60–500

produce a considerable change in the molecular dynamics of the liquid; therefore, to test rigorously a theoretical model of a liquid, or a model of a specific dynamic process in a liquid, one must perform isochoric, isothermal, and isobaric experiments. **Figure 5**, which shows the temperature dependence of the self-diffusion coefficient, D , in liquid tetramethylsilane at constant density and constant pressure, illustrates the importance of separating the effects of density and temperature on molecular motions. Four main research directions can be

identified in the high pressure NMR studies of liquids: (a) studies of self-diffusion; (b) investigations of reorientational motions; (c) studies of angular momentum behaviour; and (d) tests of applicability of hydrodynamic equations at the molecular level.

The effect of pressure on the anisotropic reorientation of acetonitrile- d_3 in the liquid state can serve as an illustrative example of high pressure NMR studies of molecular reorientation in liquids. The deuteron and nitrogen spin-lattice relaxation times of acetonitrile- d_3

Figure 4 High resolution natural abundance ^{13}C NMR spectrum of liquid 2-ethylhexylcyclohexanecarboxylate at 80°C and 500 MPa.

have been measured as a function of pressure up to 200 MPa at 23°C , using the NMR T_1 relaxation technique. Since the quadrupole coupling constants for nitrogen and deuterons in acetonitrile- d_3 are known, the experimental T_1 data are interpretable in terms of the rotational diffusion constants for motion perpendicular $D_\perp$ and parallel $D_\parallel$ to the symmetry axis.

From **Figure 6**, which plots the pressure dependence of $D_\perp$ and $D_\parallel$, it is readily apparent that $\Delta V^\ddagger(D_\perp) \gg \Delta V^\ddagger(D_\parallel)$. This experimental finding reflects the difference in frictional torques connected with the reorientation about the individual molecular axis, or more generally stated, reflects the symmetry of intermolecular potentials. The low $\Delta V^\ddagger(D_\parallel)$ value indicates that the intermolecular potential energy is largely independent of the angle of orientation about the main symmetry axis and thus the rotational frictional coefficient is very small.

Supercritical Fluids

NMR techniques can be used to study supercritical fluids as the employed pressures range from 0.1 to 80 MPa. The reason for renewed interest in the properties of supercritical fluids can be traced to the great promise of supercritical fluid extraction techniques. High pressure NMR spectroscopy can not only be used to investigate transport and intermolecular interactions in compressed supercritical fluids but an *in situ* NMR technique has also been developed for the determination of the solubility of solids in supercritical fluids.

The basic idea behind the determination of the solubility of solids in supercritical fluids is based on the radically different spin-spin relaxation rate between dissolved and solid material (T_2 , solid $\ll T_2$, dissolved). Using the 90° - t - 180° spin echo sequence with a pulse

Figure 5 Temperature dependence of self-diffusion in liquid tetramethylsilane (TMS) at (○) constant pressure and (Δ) constant density.

Figure 6 Pressure effects on the rotational diffusion constants $D_\perp$ and $D_\parallel$ of acetonitrile- d_3 at 23°C .

separation of $t \ll 1$ ms ensures that no contribution to the NMR echo signal can result from the quickly relaxing protons in the solid material. **Figure 7** gives the experimental solubilities for solid naphthalene in

supercritical carbon dioxide as determined by the spin echo NMR technique. The three isotherms measured were selected near the upper supercritical end point (UCEP) for naphthalene in CO_2 . In **Figure 7** the 58.5 °C isotherm shows a large increase in solubility at about 23.5 Mpa; the slope of the isotherm is near zero. This

indicates that one operates in close proximity to UCEP. This NMR technique can yield both solubility data and phase information when studying equilibria in supercritical fluid mixtures.

Phase Transitions in Molecular Solids

Because molecular solids exhibit significant compressibility even in the pressure range 0.1 to 900 MPa one can use high pressure NMR relaxation techniques to investigate phase transitions. The high degree of molecular rotational freedom in plastic crystals (orientationally disordered crystals) provides a good illustrative example. Adamantane, $\text{C}_{10}\text{H}_{16}$, is a saturated hydrocarbon with an fcc crystal structure in its high temperature plastic phase (α -phase), whereas at lower temperatures it undergoes a phase transition to a tetragonal structure (β -phase) in which the rotation is quenched. Taking advantage of the abrupt change in T_1 or T_2 at the phase transition provides the means of detecting the precise phase-transition pressure. At the phase-transition pressure, the T_1 of adamantane decreases abruptly by a factor of 40 in passing from the orientationally disordered plastic α -phase to the β -phase. **Figure 8** shows the pressure dependence of the proton spin-lattice relaxation times, T_1 , in solid adamantane in the α - and β -phases at different temperatures.

Figure 7 Experimental solubilities for solid naphthalene in supercritical CO_2 expressed in moles of naphthalene dissolved per litre of solution.

Figure 8 Pressure dependence of the proton spin-lattice relaxation times, T_1 , of solid adamantane in its two phases at different temperatures. The open symbols denote values obtained in the compression run, whereas the filled symbols give values for the decompression run.

The relaxation time can be expressed in terms of the rotational correlation time τ , and the

$$\frac{1}{T_1} = C \left(\frac{\omega_0 \tau}{1 + \omega_0^2 \tau^2} + \frac{4\omega_0 \tau}{1 + 4\omega_0^2 \tau^2} \right) \quad [1]$$

second moments (M^2) where ω_0 is the Larmor frequency (eqn [1]). The constant C is proportional to the proton second moment expressed in angular frequency units. For the measured T_1 one can assume $\omega_0 \tau \gg 1$ for the β -phase rotation. Then the expressions for the relaxation times

Figure 9 Normalized spin-echo amplitude as a function of time in polyethylene at 400 MPa and temperatures of 217 to 223 °C.

are as follows:

$$\begin{aligned} (1/T_1)_\alpha &= 5\omega_0 \tau C_\alpha \text{ for } \omega_0 \tau \ll 1 \\ (1/T_1)_\beta &= 2C_\beta / \omega_0 \tau \text{ for } \omega_0 \tau \gg 1 \end{aligned} \quad [2]$$

where $C_\alpha \omega_0 = 8.91 \times 10^9 \text{ radian}^2 \text{ s}^{-2}$ and $2C_\beta / \omega_0 = 2.07 \times 10^{-7}$.

Assuming that rotational motion is a thermally activated process and that the second moments are independent of temperature and pressure within our experimental range, one can obtain the activation volume $\Delta V^\ddagger(T)$ at constant temperature from the pressure dependence of $\ln(T_1)$:

$$T_1(T, P) = A(T) \exp\{\pm [\Delta V^\ddagger(T)/RT]P\} \quad [3]$$

and the activation enthalpy, $\Delta H^\ddagger(P)$, at constant pressure:

$$T_1(T, P) = B(P) \exp[\pm \Delta H^\ddagger(P)/RT] \quad [4]$$

where eqns [3] and [4] have a plus sign when $\omega_0 \tau \gg 1$, and a minus sign when $\omega_0 \tau \ll 1$.

The interesting feature of the experimental results given in **Figure 8** is the hysteresis of the observed transition pressure for the compression $\alpha \rightarrow \beta$ run and the decompression $\beta \rightarrow \alpha$ run. Analysis of this hysteresis can provide valuable information about the nature of order-disorder transitions.

Pressure Effects on Crystallization Kinetics of Polymers

NMR relaxation or line width measurements are sensitive to the degree of crystallinity in solid polymers, because the protons in the crystalline lattice experience strong dipole–dipole interactions which cause fast spin–spin relaxation and line broadening. As a result, line width and relaxation studies have been used to measure crystallinity in a broad range of polymers. The use of high pressure as an experimental variable in NMR studies of polymer crystallinity offers new details about polymer crystallization. The study of pressure and temperature effects on the kinetics of crystallization of linear polyethylene can be used as an illustrative example of this specific application of high pressure NMR techniques. One can determine the amount of amorphous polyethylene present from the initial maximum by spin-echo measurements, using the pulse sequence $90^\circ\text{--}\tau\text{--}180^\circ\text{--}\tau\text{--}\text{echo}$ with τ equal to $300\text{ }\mu\text{s}$. Figure 9, which plots the amplitude of the echo signal against time, shows the crystallization data at 400 MPa for polyethylene. Before each measurement the sample was equilibrated at the desired temperature and a pressure 75 MPa below the crystallization pressure. The very fast relaxation of the crystalline material prevented it from contributing to

the echo intensity. The isotherms as depicted in Figure 9 show the characteristic crystallization behaviour: an induction time before crystallization, a primary crystallization, and a gradual decrease in crystallization rate as the final crystallinity is approached and secondary crystallization and perfection pressures occur. The quantitative analysis of the high pressure crystallization kinetics yields information about the formation of extended crystals, the value of the Avrami coefficient, the mechanism of extended chain crystallization, and the effect of pressure on the surface energies of the crystal nuclei. High pressure NMR experiments are interesting because of their direct sensitivity to polymer chain dynamics on the microscopic scale. In this way NMR complements techniques such as dilatometry which are sensitive to bulk properties.

Mechanistic Studies of Chemical Reactions in Solution

High pressure NMR studies of various chemical reactions provide information about the reaction mechanism. Almost all reactions exhibit a characteristic pressure dependence of the reaction rate which can be used to calculate the volume of activation, $\Delta V^\ddagger$. The $\Delta V^\ddagger$, extrapolated to ambient pressure, together with the

Figure 10 Pressure–temperature phase diagram of DPPC-*d*₆₂.

partial molar volume for the reactants and products, or with the reaction volume of the overall reaction, allows one to create a volume profile that describes the volume changes along the reaction coordinate. The location of the transition state with respect to reactants and products determines the mechanism of the reaction investigated.

Both organic and inorganic reactions can be studied. Specifically, solvent and ligand exchange, and ligand substitution reactions in inorganic systems have extensively been studied by high pressure NMR techniques. **Table 2** gives the activation parameters of solvent exchange studied in inorganic systems.

Biochemical Applications

Model Membranes

Phospholipid bilayers and monolayers have important roles in nature as components of cell membranes and lipoproteins. In cell membranes, phospholipid bilayers constitute the permeability barriers between aqueous compartments. Aside from their structural interfacial roles, aggregated phospholipids modulate the functions of associated proteins and enzymes by direct binding and by physical effects. Therefore, synthetic phospholipid bilayers, in multilamellar or small bilayer vesicle forms, have become models for the study of the structural and dynamic properties of natural phospholipid aggregates.

Since the 1970s, NMR methods, in particular ^2H NMR, have been applied very effectively to investigate the biophysical properties of phospholipid bilayers. NMR experiments with high pressure and variable temperature measurements allow one to access diverse gel phases in phospholipid bilayers and to study the order and dynamics of phospholipids in bilayers as a function of volume changes.

Table 3 gives illustrative examples of high pressure NMR studies of model membranes and indicates the type of information that can be obtained from these studies. **Figure 10** shows the pressure–temperature phase diagram of deuterated dipalmitoylphosphatidylcholine, DPPC- d_{62} , as determined by high pressure NMR techniques using direct measurement of the deuteron quadrupole splitting of the methyl group and first moment analysis.

Figure 12 Phase diagram of RNase A.

Pressure Denaturation of Proteins

The relationship between the amino acid sequence and the structure of the native conformation of proteins represents the key unsolved problem of biochemistry and biology. Temperature and chemical perturbation represent the usual approach used in studies of protein stability and the folding problem. However, it is advantageous to use pressure to study protein solutions as pressure perturbs the protein environment in a controlled way by changing only intermolecular interactions. Moreover, by taking advantage of the phase behaviour of water, high pressure can lower the freezing point of an aqueous solution and allow the study of cold denaturation of proteins. The reversible pressure denaturation of bovine ribonuclease A (RNase A) can be used as an illustrative example for pressure denaturation. In this specific protein the $\epsilon 1$ hydrogen signals of the four histidine residues are well resolved from other proton peaks in the 1D ^1H NMR spectrum of the native RNase A in D_2O . These peaks have been assigned and used to investigate the folding and unfolding of the protein. **Figure 11** shows the pressure effects on the proton NMR spectrum in the histidine region of RNase A at pH 2.0 and 10 °C. As expected with increasing pressure, the intensity of the native histidine peaks decreases and at about 400 MPa their disappearance indicates that the protein is denatured. The appearance of peaks *D* and *D'* with increasing pressure signals the denaturation.

It is important to point out that during the pressure-assisted cold denaturation many proteins show significant residual secondary structure which parallels the structure of folding intermediates. It appears that

Figure 13 2D ^1H Correlation spectroscopy spectrum with presaturation pulse for solvent suppression of 2 mM sucrose at 25 °C and 475 MPa pressure recorded at 500 MHz.

pressure denaturation and pressure-assisted cold denaturation of proteins studied by high resolution NMR techniques provide novel information about the folding of proteins. In addition, these experiments allow the determination of phase diagrams for proteins. A number of protein systems have been studied in detail, confirming the formation of stabilized higher energy conformations, including ubiquitin, SUMO proteins that are ubiquitin target proteins, the human prion protein and protein G domains. **Figure 12** shows the pressure–temperature phase diagram for RNase. Above the curve the protein is in the denaturated state.

The most promising direction of the high pressure studies of proteins is the application of advanced 2D and 3D NMR techniques. **Figure 13** shows the high quality of 2D NMR spectra which can be routinely obtained at high pressures. Very often the 2D spectra obtained at high pressure offer new insights into the pressure-induced unfolding and pressure-induced dissociation of proteins when compared with results obtained by other high pressure spectroscopic techniques such as fluorescence methods.

Introduction

High resolution electron energy loss spectroscopy, known as 'HREELS', is a method for measuring the vibrational spectra of molecules adsorbed on surfaces, and some properties of clean surfaces in ultra-high vacuum. The technical aspects of the technique, theoretical basis and some examples of HREELS will be discussed.

HREELS is an 'electrons in–electrons out' spectroscopy that uses electrons typically in the 2–20 eV energy range as a probe, and detects electrons that have undergone both elastic and inelastic scattering from a surface or adsorbed layer. In practice, electrons are detected that have lost up to about 500 meV ($\approx 4000 \text{ cm}^{-1}$, $8.06 \text{ cm}^{-1} = 1 \text{ meV}$) relative to the primary beam energy in the scattering event. This range includes the most common vibrational modes of small molecules, and their overtones and combinations.

A major advantage of the HREELS method is the benefit derived from electron detection over optical detectors and methods, and a variety of scattering mechanisms. The major technical complexity of the HREELS method is the 'resolution' of 'the spectrometer', in this case the production of an intense, well-collimated beam of electrons with an energy width of less than 10 meV at the chosen primary energy (usually about 5 eV).

Detailed and comprehensive analysis of vibrational spectroscopy performed with electrons can be found in the classic work by Ibach and Mills. The details of the modern HREELS spectrometer are explored by the acknowledged master of the technique Harald Ibach in his monograph. A guide to surfaces and adsorbates studied with HREELS can be found in the proceedings of the 'Vibrations at Surfaces' Conferences, several of which are listed in the

'Further reading' section. A general introduction is often included in surface science or surface chemistry textbooks, for example the books by Lüth, Prutton and Somorjai. The internet is a resource for manufacturers of HREELS apparatus, e.g. Omicron Vakuumphysik GmbH (omicron-instruments.com) and LK Technologies, Inc. (lktech.com).

The ideal surfaces for study are smooth, metal single crystals that are clean and well ordered on an atomic level. Such a specimen is 'highly reflecting' and maintains the signal in the specularly reflected electron beam. Practical surfaces range from polished single crystals, cleaved surfaces and semiconductor wafers to polycrystalline metals. The adsorbate can be a monoatomic or molecular species, such as atomic hydrogen, or large macromolecules and polymers. Insulators can be measured in special circumstances.

Many aspects of surface science and surface spectroscopy are concerned with the geometrical structure of surfaces, the composition of the surface and the identification of adatoms that may be present. Vibrational spectroscopy is a method for direct measurement of specific *chemical bonds* of adsorbed atoms and molecules, both between the adsorbate and the surface and the adatoms themselves. In the early days of HREELS, the 1970s, an added attraction for this type of spectroscopy was the ability to observe adsorbate–surface bonding modes (often $< 125 \text{ meV} = 1000 \text{ cm}^{-1}$), because the infrared spectrometers of the day used 'grating' spectrometers, and IR detectors that were useful only above 1600 cm^{-1} . The low cost and versatile Fourier transform infrared spectrometer (FTIR) and improved detector technology have eclipsed HREELS for routine surface chemical bond analysis. There are, however, some surface processes that can only be observed with electrons. Some diagnostic benefits that are related to the scattering mechanisms operative in HREELS continue to be useful for surface science. It should be noted that HREELS is usually performed on a 'known' adsorbate, with a focus on the details of a specific adsorption system. HREELS is seldom used for the identification of 'unknown' adsorbate species.

Basic Concepts and Requirements

Method

In HREELS experiments, electrons produced by a thermionic emission source are passed through an

electrostatic monochromator, so that an electron beam of narrow angular width and narrow energy spread is produced that is then scattered from a surface. Electrons which scatter from the surface are analysed with an electrostatic analyser (similar or identical to the monochromator) and detected with an electron multiplier. The HREELS data is acquired as 'count rate' (= current exiting the analyser) *vs* the energy loss range scanned, from E_p to $(E_p - E_{\text{scan}})$, for example from 5 to 4.5 eV, that includes E_{loss} . In a typical HREELS spectrum, a 'no-loss' or 'elastic' peak will be observed in the specular scattering direction with energy E_p and an FWHM of ΔE_p , and loss peaks will be observed in accordance with certain selection rules, at energies $E_{\text{loss}} = E_p - \hbar\omega$, where ω is the frequency of oscillation of the vibrational mode, and an energy width of $\Delta E_{\text{loss}} \geq \Delta E_p$. A general schematic is shown in **Figure 1**.

The 127° cylindrical capacitor analyser is currently the most advanced device for HREELS. The functional components of the HREELS spectrometer are shown as a block diagram in **Figure 2**; a representative schematic of a 127° cylinder spectrometer is also shown in **Figure 3**. There are various other HREELS instrument designs with individual merits.

Figure 1 An overview of high resolution electron energy loss spectroscopy. Top left: the incident electron beam is shown as a narrow, intense peak on the intensity *vs* energy loss axes. The specularly reflected beam is shown with loss peaks due to adsorbed molecules, with modes $\hbar\omega$. Centre: The scattering mechanism is illustrated with the three diatomic molecules 'adsorbed' on the surface with perpendicular and parallel orientation relative to the surface. Mode ω_1 has a dynamic dipole moment p_0 which is perpendicular to the surface, and induces a second image dipole in the same direction, so that the electron scatters from a combined dipole moment of $2p_0$. This is the dipole scattering process. The mode ω_2 is parallel to the surface, and the induced image dipole cancels the molecular dynamic dipole moment. The mode is 'screened' and is not present in the spectrum if there is no impact contribution to the scattering. Mode ω_3 is shown with the dynamic dipole moment equal to zero (the orientation is not relevant). The mode will be observed as an 'impact' mode.

HREELS operation requires specialized precautions and procedures. Many are determined by the trade-off between the spectrum intensity and resolution, the production of the low-energy electron beam, and mechanical restrictions. Practical size limits for HREELS analysers are about 100 mm radius. The thermionic electron source has an energy width of the order of 1 eV. Only a small fraction of the emitted current is passed by the monochromator. Electrons with 5 eV kinetic energy are easily deflected by stray electric and magnetic fields. All of the spectrometer parts are coated with graphite to create a uniform work function on parts in the electron path. The spectrometer itself is usually baked after the UHV chamber itself is baked, so that non-uniformities in the analyser due to unwanted adsorbed contaminants are removed. No magnetic parts are allowed in the vicinity of the spectrometer. Most HREELS chambers are doubly shielded against magnetic fields ($<1 \text{ mG cm}^{-1}$ for the residual homogeneous DC field), and all of the electric potentials applied to the spectrometer are shielded and regulated to within a few percent of 1 mV. The specimen must be introduced between the HREELS monochromator and analyser with no vibration, no magnetic parts, and no 'stray' potentials such as those that may arise from charging of ceramic insulators, etc. It is often beneficial to be able to cool the specimen to 100 K or lower, and sputter and heat the surface for cleaning.

The 'mechanics' of HREELS is now manageable using personal computer-based spectrometer control. Typical spectral resolution of modern instruments is 1–5 meV. At the lower end of this range physical effects due to natural

Figure 2 The necessary parts of an HREELS spectrometer: e, electron source, L, lens to focus electrons onto the entrance slit of the monochromator, M, which can have one or two stages. Another lens, L, focuses the beam onto the sample, S. A lens, L, focuses electrons scattered from the surface onto the entrance slit of the analyser, A, which can also have two stages. The electrons are counted at the detector, D.

Figure 3 A typical 127° two-stage cylindrical capacitor analyser. The individual parts correspond to the components described in **Figure 2**. Usually, one of the arms of the spectrometer is made to rotate in-plane about the specimen axis to allow off-specular measurement.

vibrational line widths are observable. In the early days of HREELS, single-pass cylindrical (127°) capacitor spectrometers, both fixed and with a movable analyser or monochromator, double-pass cylindrical (127°) capacitor analysers, spherical capacitor spectrometers and even some dual-use photoelectron spectrometers with enhanced resolution ranges were used, with spectral resolution in the 7–12 meV range.

Scattering Mechanism

A non-mathematical description of the HREELS scattering mechanisms will be given briefly. In ‘dipole scattering’ an incident electron scatters from the long-range oscillating dipole field that arises when the adatom oscillates on the surface. In this mode, collecting only electrons scattered into the near-specular direction, HREELS information is essentially identical to data obtained from surface infrared vibrational spectroscopy. Electrons scatter from the long-range dipole fields of elementary excitations of the solid or adsorbate. A change in the dipole moment during the vibration is detected; consequently, there must be a non-zero dipole derivative with respect to time or a ‘dynamic’ dipole moment. **Figure 4** illustrates the scattering geometry for HREELS.

Energy and momentum conservation are simply expressed as: $E_{\text{loss}} = E_p \pm \hbar\omega_s$, where the momentum of the incident (‘primary’) electron is k_p and k_s for the scattered electron, so that

$$E_{\text{loss}} = \frac{\hbar^2 k_s^2}{2m} = \frac{\hbar^2 k_p^2}{2m} \pm \hbar\omega_s(Q_{\parallel})$$

Figure 4 A schematic representation of specular reflection (θ) and momentum conservation in HREELS scattering events. The momentum parallel to the surface is conserved. The quantity $Q_{\parallel}$ is the parallel momentum transfer, and determines the angular deflection $\Delta\theta$. The incident electron is characterized by velocity and momentum components v and k_p , k_s is the scattered electron momentum, and Δk_z is the change in momentum in the z direction.

where $Q_{\parallel}$ is the momentum transfer parallel to the surface, and the vector

$$k_{s\parallel} = k_{p\parallel} \pm Q_{\parallel} + G_{\parallel}$$

where G is a reciprocal lattice vector (usually, $G_{\parallel} = (0,0)$, $G_{\parallel} \neq (0,0)$ is diffraction). The dipole excitations have a long-range potential, which ensures that the interaction time is large and that the probability for scattering is also high. Both losses and gains are possible.

In order to pass through the analyser entrance slit, the angular deflection (momentum transfer) caused by the collision must be small enough to keep the electron within a few degrees of the specular direction. An estimate for this deflection in dipole scattering is given by $\delta\theta = \hbar\omega_s/2E_p$, so that for 200 meV loss energy and 5 eV primary energy, the deflection is of the order 1° .

It is possible to detect electrons that are not scattered into the specular direction, either by rotation of the sample or moving the HREELS analyser or monochromator. The possibility of data collection ‘off specular’ sets HREELS apart from its optical counterparts. The most important ‘off-specular’ scattering mechanism is known as ‘impact’ scattering. This name is intended to denote a *short-range* inelastic scattering mechanism unrelated to the long-range dipole scattering mechanism. (The elastic ‘impact’ process is electron diffraction.) As a functional, but not entirely correct, definition, any intensity that remains in the ‘off-specular’ direction spectrum is termed ‘impact’ scattering. The intensity of ‘impact modes’ for a mode u is $I_{\text{impact}} = \frac{1}{2}(Q \cdot u)^2 I_0$, where u is the displacement of the atom from its equilibrium position, Q is the change in wavevector of the electron, and I_0 is the elastic scattering intensity. The wave vector transfer Q can be large, so that impact scattering is not restricted to the specular direction. Experimentally, the intensity of the ‘dipole’ loss peaks exhibits the same dependence on off-specular angle as the elastic peak intensity. As a consequence, impact modes can be much more intense relative to the dipolar contribution at high off-specular angles. Because most analysers are constructed for about 50° incidence from the sample surface normal, $25\text{--}30^\circ$ off specular are the largest practical values.

A detailed examination of the electron–adatom–surface interaction must be divided into several parts: either direct scattering from the adatom in the specular direction, specular reflection at the surface followed by (forward) scattering from the adatom, or adatom scattering followed by specular reflection. Multiple combinations of these individual events can also result in an electron detected at the analyser. For each interaction, there are elastic and inelastic versions. A schematic representation is shown in **Figure 5**. To date, HREELS theory has dealt only with the large divisions of scattering events into elastic/inelastic and dipole/impact processes. Other phenomena have been observed, and can be regarded as significant scattering

Figure 5 A schematic representation of scattering phenomena that can be observed in HREELS spectra. The diagram notation is loosely based on McRae and Ibach and Mills. The incident electron comes from the left. In each diagram, a time-reversed event is often possible, and these are not shown. Events that involve small-angle forward scattering preserve the specularly scattered intensity, and contribute to HREELS; large-angle scattering contributes less, and some of these diagrams are omitted. In (a) the no-loss, specular scattering from a surface is shown (a filled, black circle at the surface). The no-loss or elastic peak is a result of process (a). Process (b) represents dipolar elastic diffuse scattering (denoted with an arc on the exit beam), such as observed for no-loss peak intensity decreases upon adsorption (see **Figure 14**, **Figure 15b**). Diagram (c) shows a resonant process, where an electron is scattered elastically into and out of a surface resonance (wavy line) in the specular direction. An example is a clean-surface reflectivity measurement (see **Figure 17**) with a surface resonance and/or image potential states. In these processes, in order to scatter into a weakly bound surface resonance, energy conservation by an Umklapp process may occur. Diagram (d) shows the elastic, specular reflection at the surface followed by a loss (open circle) and small angle deflection. This is 'dipole scattering'; the reverse, loss then reflection, is equally important, but not shown. Most HREELS spectral features are due to processes (a) and (d). Diagram (e) shows an unlikely, high-angle scattering, inelastic process that is detected in the specular direction. The process (f) represents multiple, small-angle inelastic scattering followed by specular reflection, but at angles unrelated to the incident electron, which results in a 'diffuse' reflected beam, even though each inelastic scattering event was nearly specular (see **Figure 14**, HCN 'ice'). Process (g) represents a molecular resonance. The electron scatters out of this resonance isotropically. The diagrams (h) and (i) show combinations of inelastic scattering and surface resonances with specular reflection. Process (j) represents diffuse (open square box) impact scattering followed by an inelastic loss event. Many more combinations of these mechanisms are observed in special cases.

Figure 6 The HREELS spectra of saturation coverage of adsorbed NO, CO and CN on Pd(111) and Cu(111). In each case, a metal-adsorbate ($M-R$, $R=NO, CO, CN$) mode and a molecular stretching mode ($\nu(A-B)$) is observed. For NO and CO, the relative bond order is observed in the position of the $\nu(N-O)$ and $\nu(C-O)$ stretching modes; the relative strength of the metal-adsorbate and molecular stretching dynamic dipole moments is seen in the ratio of the $M-NO$ to $\nu(N-O)$ modes, 1:12; $M-CO$ to $\nu(C-O)$, 1:2. For CN on Pd(111) and Cu(111), the $\nu(C-N)$ mode is parallel to the surface. The difference in charge transfer and bond strength is seen in the ratio $M-CN$ to $\nu(C-N)$ which is 20:1 for Pd and 190:1 for Cu. The spectra are not normalized to each other, and are not intended for absolute comparison.

types observed in HREELS spectra, even if they are not entirely distinct from the dipole and impact mechanisms (dipole or impact scattering may still be *part* of the process). Molecules with large static dipole moments have a large scattering cross section, so that 'dipole' scattering from a partially covered surface may cause diffuse scattering of electrons, much like a rough surface causes diffuse optical reflection. There are many forms of resonance scattering: an electron can be scattered into a surface state or resonance, causing an increased residence time at the surface, which can influence spectral features. The incident electron can induce surface resonances, such as image potential states, which also capture the electron at the surface for increased residence time and possible non-specular scattering. Molecules can capture electrons in 'negative ion resonances', which also have consequences for peak intensities and multiple or combination scattering peaks. Ionic crystals and semiconductors can have surface phonon modes in the energy range which is accessible to HREELS. Some illustrative examples are given below.

Selection Rules and Symmetry

Selection rules for dipole scattering from surface-adatom symmetry configurations follow those for IR spectroscopy. Relevant discussion can be found in Ibach and Mills, and general references on symmetry, normal modes and selection rules in spectroscopy. Briefly, for dipole scattering, those modes with a non-zero dynamic dipole moment are allowed. Because the electric field induced by the incident

Figure 7 HREELS spectrum of OH and Ag(110) [top], and O [bottom]. A modern HREELS spectrometer was used with 2 meV elastic peak width. Note phonon modes and the width of the $\delta(\text{O-H})$ relative to the $\nu(\text{Ag-OH})$ mode.

Figure 8 The reorientation of adsorbed CN on oxygen pre-covered Cu(111). The bottom spectra (a) and (b) show 100 L ($L = 1 \times 10^{-6} \text{ torr s}^{-1}$) C_2N_2 dissociatively (as CN) adsorbed on Cu(111) at 300 K. The loss and gain of the CN-Cu adsorbate-metal frustrated translation is clearly evident at $\pm 24 \text{ meV}$. Spectrum (c) shows the Cu(111) surface after 60 L oxygen exposure at 300 K. Spectra (d) and (e) show the surface after exposure to 20 L C_2N_2 after the oxygen exposure. The CN stretching mode is more intense, and shifts from 254 to 266 meV, and shows a 'dipolar' angular dependence. Reprinted from *Journal of Electron Spectroscopy and Related Phenomena*, 44, M.E. Kordes, HREELS of the adsorption and reaction of CN on clean and oxygen covered Cu (111), 154, 1987, with permission from Elsevier Science.

electron is perpendicular to the surface, only dipoles with a component in this direction can interact with the incident electron. This implies that the normal component (z) of the dynamic dipole moment must be totally symmetric with respect to all of the symmetry operations of a point group. Often, the rule is stated that fundamental modes observed in dipole scattering must belong to the A_1 , A' and A totally symmetric representations. This is true for any surface that can effectively screen the parallel dipole moment of the adsorbate motion (most often, metals). The possibility remains that a mode exists that is normal to the surface, but has no dynamic dipole moment, or that a parallel mode that belongs to the correct representation (i.e. dipole allowed) could be observed due to charge transfer to orbitals that create a dynamic dipole moment normal to the surface.

The impact scattering selection rule is more complex, and can be found in Ibach and Mills.

Group frequencies for adsorbates are usually similar to those determined from IR spectroscopy for coordination compounds and from bulk measurements. Several reference works of this type are available.

Applications

Clean Surfaces

In the 2–20 eV range, surface excitations related to the dielectric response function and free carrier density of the surface are observed. Clean-surface loss spectra can include features due to surface phonons, surface plasmons, interband transitions and surface optical phonons in ionic insulators. The probe depth for these phenomena in HREELS is about 10 nm. Transitions between surface

Figure 10 Carbonate formation on Ag(110). The new HREELS spectrometers can distinguish isotopically labelled molecular vibrations. The shifts are complex and must be calculated from first principles.

states can also be observed in the loss spectrum. Some examples are given in the section related to hydrogen adsorption and surface states below.

Clean surfaces can be probed with electrons to determine vibrational, electronic and structural properties. Diffraction with electrons is well known; practical low-energy electron diffraction is performed with display analysers in the 50–500 eV range. Bulk electronic excitations such as plasmons are usually observed in the 10–50 eV range. While some HREELS spectrometers are capable of 200 eV primary beams for this kind of measurement, plasmons are more often investigated with analyser types designed for higher energy, such as those used for Auger electron spectroscopy or X-ray and ultraviolet photoelectron spectroscopy.

Adsorbates on Surfaces

Chemisorbed molecules

Literally hundreds of adsorbate–surface systems have been investigated in the years over which HREELS measurements have been made. A selection of work will

be presented that represents the major principles of HREELS and what can be learned from this technique. It is not comprehensive, and an electronic literature search program is recommended for up-to-the-minute references to the 'state of the art'. Modes are often denoted by Greek letters, the most common are ν for stretching modes, δ for bending modes and ρ for wag, scissor or twisting modes. Aromatic molecules have several different labelling conventions.

In **Figure 6** the relative importance of charge transfer upon adsorption, bond order, the dipole moment perpendicular to the surface and screening is shown in a

Figure 13 HREELS spectrum of Fomblin Y on polycrystalline molybdenum. The CF, CF₂, CF₃ modes are unresolved, at 157 meV. Overtones at 314 and 471 meV are observed. Other modes: $\delta(\text{OCO}) = 67$ meV, $\nu(\text{OCO})$ or $\nu(\text{CC}) = 92$ meV, the mode at 125 meV is characteristic of Fomblin Y, a stretching mode in a monomer segment, $\nu(\text{CF}_3\text{--C--CF}_2)$.

comparison of three isoelectronic adsorbates on Pd and Cu surfaces. In the earlier discussion (**Figure 1**), the adsorbate-surface modes were neglected for clarity. In **Figure 6**, NO, CO and CN HREELS spectra are shown; these adsorbates are present on the surface as NO⁺, CO and CN⁻. Each of these diatomic molecules will have a stretching mode and a molecule-surface vibrational mode known as a 'frustrated translation' perpendicular to the surface. For NO and CO, the axis passing through the molecule along its length is perpendicular to the surface; for CN on Pd, the C-N axis and the CN stretching motion are parallel to the surface and partially screened, on Cu the CN motion is again parallel to the surface and hence very weak, but the Cu-CN⁻ mode (near the elastic peak) is very intense due to the motion of the *entire* ion perpendicular to the surface. A gain is also observed. Adsorbed NO is also an ion, but the difference in charge transfer compared to adsorbed CN is significant, as is revealed by the difference in the adsorbate-metal modes.

Using a modern spectrometer with better resolution, **Figure 7** shows a spectrum of an ordered OH overlayer

Figure 14 HREELS spectrum of 50 L HCN exposure at 100 K on Pd(111). The libration mode λ , the HCN bending mode δ , and the CN and CH stretching modes ν_{CH} and ν_{CN} are identified with some of their combinations. The vertical ladders show some of the Poisson series for the libration mode.

on Ag(110) generated by the reaction of water with pre-adsorbed oxygen (the oxygen spectrum is the lower curve in **Figure 7**). The OH radical is stabilized by the chemisorption bond to the silver surface and forms an ordered (1×2) layer. Note that the $\delta(\text{O-H})$ mode is broadened relative to the elastic peak, and that phonons due to the silver surface are observed as both losses and gains ($45, 83 \text{ cm}^{-1}$).

In **Figure 8**, the use of dipole selection rules to determine molecular bond orientation is shown. On Cu(111), for adsorbed CN, the CN axis is parallel to the surface. The C-N stretching mode is weak (screened), and measured to lie at 254 meV (2045 cm^{-1}); the Cu-CN mode is very strong. When CN is adsorbed on an oxygen pre-covered surface, the C-N stretching mode is observed at a higher frequency, 266 meV (2140 cm^{-1}), and several times more intense. No new modes are observed, so that an O-CN bond is not formed, and the Cu-CN mode is reduced in intensity. These spectra are interpreted to indicate that the CN molecule initially bonds to the surface as an ion, with the CN axis parallel to the surface. In the presence of pre-adsorbed oxygen, the vertical bonding geometry, with the CN axis perpendicular to the surface, is observed. The shift in frequency is consistent with this observation, and the fact that oxygen adsorbs on Cu as O^- and thereby alters the

Figure 15 (a) The intensity of the no-loss peak as a function of HCN exposure in Langmuir at 100 K. The dotted line is with the spectrometer optimized to compensate for work function changes, the solid line is 'as measured'. (b) The angular width of the no-loss peak, measured for clean Pd(111), at the first minimum, 2 L, and at the first maximum in **Figure 9a**, about 4 L.

CN bond geometry. Similar orientation effects are observed for molecules such as pyridine and benzene, thiophene, furan and pyrrole. A molecule may be observed to reorient as a function of surface coverage (i.e. a second layer), or as a function of the packing density of the chemisorbed layer (reorientation in the first layer).

Another useful diagnostic method in HREELS (and vibrational spectroscopy in general) is the use of isotopic substitution to identify a particular vibrational mode by substitution of a different mass isotope and determining the shift of the mode frequency upon substitution. In **Figure 9**, the HCN molecule adsorbed on Pd(111) at 300 K is exposed to deuterium while the HREELS

Figure 16 Specular and off-specular HREELS spectra of H adsorbed on Pd(100). The perpendicular mode is at 63 meV. The parallel mode is at 76 meV. Reprinted from *Surface Science*, 178, M.E. Kordesch, Surface resonances in vibrational spectroscopy of hydrogen on transition metal surfaces: Pd(100) and Pd(111), 578–588, 1986, with permission from Elsevier Science.

spectrum is monitored. New modes are observed; the C–H mode is replaced with a C–D mode at a new frequency related to the change in the mass of D relative to H. The altered mass of DCN relative to HCN also shifts the bending and molecule–substrate modes.

New HREELS spectrometers are able to distinguish shifts due to oxygen, carbon and nitrogen isotopes, among others, with no alteration in the adsorption geometry, simplifying the interpretation of the spectra. The shifts are not as simple as the H/D substitution, and must be calculated from first principles. In **Figure 10**, the reaction of isotopically labelled CO_2 with preadsorbed O to form adsorbed carbonate on Ag(111) is shown, with the relative shifts of the peak positions due to the differences in isotope masses. The assignment of the carbonate modes is included in **Figure 11**. The frequencies are for $(\text{CO}_3)^-$ ions in solution. The delta-mode is not seen in specular HREELS. The extrinsic modes of CO_3 are at 229 and 266 cm^{-1} for the normal carbonate; the higher mode is assigned to the substrate stretch, the lower mode is a libration mode. The losses around 330 to 311 cm^{-1} are due to residual oxygen not bonded in a carbonate, shifted in accordance with the isotopic substitution, because the layers are prepared by pre-adsorption of ^{18}O or ^{16}O at 300 K and forming in the (4×1) reconstructed surface. During the reaction (exposure to CO_2 , $^{13}\text{C}^{16}\text{O}_2$ or $^{12}\text{C}^{18}\text{O}_2$) only part of the oxygen reacts; the rest is compressed into the higher coverage reconstruction, the

(2×1) surface, and survives. The LEED pattern is a superposition of $(2 \times 1)\text{O}$ and $(1 \times 2)\text{CO}_3$.

Reactions can be observed in HREELS, most commonly the dissociation of large molecules into smaller fragments after heating. A correlation with temperature-programmed desorption is very useful. The reaction of small molecules to form larger compounds is also of interest. In **Figure 12**, the reaction of benzonitrile with oxygen on Cu(111) to form an ‘N-bonded oxide’ (or fulminate) is shown. The two reactants are adsorbed at low temperature, where no reaction occurs. The substrate is heated to successively higher temperatures and then observed in HREELS. The benzonitrile is adsorbed with the plane of the benzene ring parallel to the surface, and the benzene–CN bond is observed to remain intact in the spectrum during the reaction. At 170 K the new CN–O stretching band is observed at 171 meV (1370 cm^{-1}). This example illustrates how HREELS is applied to specific chemical bonds.

The deuterium substitution reaction mentioned above raises the question of time-resolved HREELS. Some attempts have been made to use parallel detection methods in HREELS, so that time-resolved spectra can be acquired. The experimental realization of this method is complex; Wilson Ho has pioneered the implementation of time-resolved HREELS, and some results are given in his review. FTIR instruments may prove more efficient in this area.

Large molecules pose a difficult interpretation task for HREELS. A molecule with many, closely spaced modes will produce a spectrum with unresolved vibrational modes. A large molecule may not have a single adsorption geometry, making the application of selection rules difficult. Some success has been achieved with polymers. An example is shown in **Figure 13**; the observation of Fomblin Y, a perfluoropolyether oil, on polycrystalline molybdenum. The polymer has a molecular mass of over 10 000, and contains several different monomer constituents. The fluorine groups, and some pendant group modes, can be observed. The individual fluorine groups, CF, CF_2 , CF_3 are not usually resolved (157 meV , 1256 cm^{-1}), even in IR spectra, but several overtones of the C–F modes are observed. Useful information can still be obtained, even from very large molecules or polymers.

As the surface coverage increases, as in a condensed multilayer ‘ice’, the dipole selection rules are relaxed, because the screening of parallel modes is less effective in the outermost layers of the ‘ice’, because these layers are further from the surfaces. In **Figure 14**, an HREELS spectrum of HCN multilayer ‘ice’ condensed on Pd at 100 K is shown. The HCN molecule has three normal modes, $\nu(\text{C–H})$ and $\nu(\text{C–N})$ stretching modes along the molecule axis, and a doubly degenerate $\delta(\text{H–CN})$ bending mode. There are at least 20 modes evident in

Figure 17 Surface reflectivity of Pd(111) and Pd(100) with and without adsorbed H. The reflectivity is on log scale. The addition of hydrogen shifts and intensifies the lowest energy surface resonance on Pd(111) (5.5 eV). The sharp drop in reflectivity at 8 eV corresponds to the emergence of a surface diffraction beam, and opens a new channel for electron interaction with the surface. The image potential states are just below this emergence threshold. On Pd(100) the curves are similar, but the energy scale is reduced due to the different crystal structure of the surface and different-sized surface Brillouin Zone. Reprinted from *Surface Science*, 178, M.E. Kordesch, Surface resonances in vibrational spectroscopy of hydrogen on transition metal surfaces: Pd(100) and Pd(111), 578–588, 1986, with permission from Elsevier Science.

this spectrum. At low temperature, HCN is thought to form hydrogen-bonded chains (a ‘catamer’). The HCN molecule in the chain has a strong static dipole moment, and the motion of the chains parallel to the surface (a libration, or frustrated rotation) serves to induce a strong dynamic dipole moment in the direction perpendicular to the chains. The libration is observed along with the usual HCN modes.

The HCN ‘ice’ spectrum illustrates several aspects of HREELS. The strong dynamic dipole moment due to the libration mode causes multiple scattering from the molecules, so that there are several replica ‘primary’ peaks almost as intense as the elastic peak. Consequently, each of the usual HCN loss peaks generates a spectrum with the same spectral intensity relationships as the ‘no-loss’ peak. The multiple scattering intensities follow the Poisson relationship for multiple random events. The chain formation distorts the molecular potential, so that

overtone and combinations are possible due to anharmonic coupling of the normal modes.

A common phenomenon observed upon adsorption of molecules is the decrease in the elastic peak intensity as a function of coverage. **Figures 15a and b** show the intensity and angular width of the elastic peak as a function of HCN coverage on Pd. The intensity correlates well with layer formation on the surface, much like RHEED oscillations. Even though the scattering mechanism is decidedly ‘dipolar’, the surface is made ‘rough’ by a partial coverage of HCN. As the surface layer is completed, the specular beam sharpens, but the phenomenon is repeated as the second layer adsorbs.

In dielectric layers, where a surface phonon mode may occur, or in ionic crystals, multiple scattering from the surface phonon mode can result in Poisson ‘replicas’ of the no-loss peak. These modes are referred to as ‘Fuchs–Kliwer’ modes; they are a general feature of

Figure 18 The intensity of the parallel and perpendicular H vibrational modes at different primary energies on Pd(111). The maxima in the vibrational enhancement correspond to minima in the electron reflectivity curves. Reprinted from *Journal of Electron Spectroscopy and Related Phenomena*, 38, M.E. Kordesch, Surface resonances on Pd(111)/H observed with HREELS, 289–298, 1986, with permission from Elsevier Science.

HREELS spectra of ionic and polar materials, and metal oxides. Ordered overlays on surfaces can also exhibit collective modes, but at submonolayer coverages the HREELS loss peaks are due almost exclusively to single oscillations of the fundamentals. Substrate (silver) phonon modes are shown at 10 meV (83 cm^{-1}) in **Figure 7**.

Single crystals are understandably the most interesting substrates for surface science, because other spectral data and calculations are made easier by an ordered surface. For technology, however, such as lubrication studies, or adhesion, a polycrystalline surface is more relevant. Some success has been achieved with polycrystalline metal surfaces, but a case-by-case test for suitability is necessary. The spectrum in **Figure 13** (Fomblin Y perfluoropolyether) was nearly identical to that obtained on Mo(100), with the exception of a slightly broader elastic peak.

Hydrogen

Hydrogen is difficult to detect with many surface analytical methods. In HREELS, the adsorption of hydrogen and deuterium is relatively easy, both experimentally, and

in ‘first instance’ interpretation of the spectral features. In the case of hydrocarbons and other molecules, the CH, NH or OH modes are often studied. The CH modes in aromatic molecules are observed to be partially ‘impact’ modes. **Figure 7** shows several OH modes; in particular it is possible to observe natural line width broadening for the $\delta(\text{O-H})$ mode on Ag(110) with the newer high resolution spectrometers.

On many transition metals, hydrogen adsorbs dissociatively, with atomic hydrogen adsorbed in high-symmetry sites. The modes perpendicular to the surface are usually dipole modes; parallel, frustrated translation, modes have some impact scattering character and can be observed in off-specular spectra. **Figure 16** is an example of specular and off-specular HREELS spectra of H adsorbed on Pd(111).

Atomic hydrogen is small and adsorbs near to the surface. H modes can directly couple to surface states and resonances, such as image potential states, that may overlap in the near-surface region. An empirical verification of this phenomenon, observed on several metals (Pd, Pt, Rh, Ru), is the enhancement of surface resonances by adsorbed H, and the enhancement of H vibrational modes at primary energies which correspond to the population of the surface resonance with electrons from the incident HREELS beam. In **Figure 17**, the reflectivities of the Pd(111) and (100) surface with and without adsorbed hydrogen are shown. The relative intensities of the H frustrated translation and rotation (perpendicular and parallel) modes are shown in **Figure 18**.

Symbols

B_e	equilibrium rotational constant
B_{v_i}	rotational constant in the v_i vibrational mode
B_x	rotational constant
D, d	quartic centrifugal distortion constants
$G_0(v_i)$	vibrational term value when the energy levels are referred to the ground state as zero
H, h	sextic distortion constants
k_B	Boltzmann constant
k_f	rate constant of the forward reaction
K_c	equilibrium constant
r_{C-H}	interatomic distance between C and H atoms
T	(thermodynamic) temperature
v_i	vibrational quantum number
W	Fermi resonance parameter
x_{ij}^0	vibrational anharmonic constants when the energy levels are referred to the ground state as zero
α_i	rovibration interaction constant
$\Delta_r H^\circ_{298}$	standard reaction enthalpy
$\Delta_r S^\circ_{298}$	standard reaction entropy
$\Delta\nu$	full line width at half intensity maximum
μ	dipole moment
$\tilde{\nu}(v_i)$	transition wavenumber in vacuum
ξ	Coriolis constant
$\tilde{\nu}$	wavenumber in vacuum
$\nu\tilde{\nu}_0$	wavenumber of a rovibrational band origin
τ	relaxation time
ω_i^0	harmonic vibration wavenumber when the energy levels are referred to the ground state as zero

The IR region of the electromagnetic spectrum extends from the visible ($\lambda \cong 800 \text{ nm}$, $\tilde{\nu} \cong 12\,500 \text{ cm}^{-1}$) to the sub-mm waves ($\lambda < 1 \text{ mm}$; $\tilde{\nu} > 10 \text{ cm}^{-1}$) and the IR photon carries an energy in the $2.48 \times 10^{-21} - 1.99 \times 10^{-24} \text{ J}$ range. This is also the energy exchanged by an atom or a molecule when IR radiation is emitted or absorbed. The interaction of the IR radiation with particles corresponds to transitions between rotation–vibration energy levels in molecules or between Ryberg levels in atoms.

High-resolution IR spectroscopy is confined to the study of atoms and molecules in the gas phase at low pressures, where the interaction energy between particles is orders of magnitude lower than in the condensed phases. The intermolecular interactions broaden the energy levels, and, consequently, the spectral lines, preventing the observation of finer details in the spectra. In the IR region the width of the spectral lines in the gas phase is caused mainly by the Doppler effect and by the broadening due to collisions. The concept of high resolution in IR spectroscopy has changed with the introduction of new experimental techniques such as FT-spectroscopy and laser techniques. Presently, an instrumental resolution of $2 \times 10^{-3} \text{ cm}^{-1}$ (measured as FWHM) or higher is achievable with commercial FT interferometers in the $10\text{--}4000 \text{ cm}^{-1}$ range: this is comparable to the Doppler line width for a molecule with a mass of 50 amu at room temperature, calculated using the equation:

$$\Delta\tilde{\nu} = 2\tilde{\nu} \left(\frac{2T k_B \ln 2}{mc^2} \right)^{1/2} \quad [1]$$

where k_B is the Boltzmann constant, m is the particle mass, T is the absolute temperature and c is the speed of light. Thus the Doppler width can be assumed as the limit of high-resolution FTIR spectrometers that use a broadband radiation source of low spectral brightness. With the introduction of lasers in the infrared, sub-Doppler resolution can be obtained using the saturation Lamb-dip or other specialized techniques. Sub-Doppler resolution can also be performed with molecular beams or in supersonic jet expansions, where molecules are rotationally and vibrationally cooled to a few K. Moreover, the enhancement of sensitivity of the new experimental techniques has made possible the detection and analysis of many unstable or transient species such as van der Waals complexes, free radicals and ions.

The main applications covered in this study are the accurate determination of rotation and rotation–vibration molecular energies; the determination of the molecular geometry of simple molecules; the evaluation of force field and of the vibration– and rotation–vibration interactions; the measurement of pressure broadening and pressure shift of the spectral lines; the determination of electric dipole moments via laser-Stark spectroscopy; the studies of intramolecular dynamics; the calculation of

rate constants, equilibrium constants and other thermodynamic data; the evaluation of relaxation times.

Rotational and Rovibrational Energies

The results of the analysis of a high-resolution IR spectrum of a molecule is usually a large and accurate set of molecular constants. With these constants, rotational and rovibrational energy levels can be calculated within the range of the quantum numbers of the transitions from which they have been obtained. This is the primary application of high-resolution gas phase spectra in the IR region. The results of the analysis of the $\tilde{\nu}_1$, $2\tilde{\nu}_2$ and $2\tilde{\nu}_3 + \tilde{\nu}_6$ IR bands of COF₂ are presented as an example in **Table 1**. The wavenumbers of about 3200 spectral lines have been measured and assigned to specific rovibrational transitions, identified through the rotational quantum numbers of the lower and upper states of the transition. After the assignments a least-squares analysis was performed, where the parameters of **Table 1** and their standard deviations were determined.

The most important molecular constants are $\tilde{\nu}_0$, the energy of the vibrational levels above the rotationless ground state and the rotational constants B_x , B_y and B_z .

The centrifugal distortion constants, D and d , H and h , are orders of magnitude smaller than B and account for the deviations from the rigid rotor energy levels. The constants W are necessary to reproduce the measured spectrum since the $\tilde{\nu}_1$ and $2\tilde{\nu}_2$ states are in Fermi resonance. The constants ξ take into account the Coriolis interaction between the $\tilde{\nu}_1$ and $2\tilde{\nu}_3 + \tilde{\nu}_6$ states. For the latter state no transitions have been observed and its constants have been obtained from the perturbation induced on the levels of $\tilde{\nu}_1$. The RMS in **Table 1** is the standard deviation normalized to a single rovibrational transition of the calculated and measured spectrum. This quantity should be very close to the precision of the wavenumber measurement if the theoretical model used for the analysis is satisfactory.

Determination of Molecular Geometry

Accurate molecular geometries can be obtained from the analysis of the high-resolution IR spectra. The analysis of rovibrational spectra provides, among other important data, the rotational constants of the molecules, which in turn allow the determination of the principal moments of inertia and, eventually, of the molecular geometry. rotational spectroscopy provides the same information, usually for the ground state, except when the molecule under study has no permanent electric dipole moment. The principal moments of inertia are related to the bond lengths and bond angles of the molecule by equations that vary according to the geometry. The equilibrium geometry corresponds to the minimum of the potential energy surface of the molecule. Owing to the zero-point energy this minimum does not correspond to a stationary state of the molecule. The rovibrational analysis of fundamentals and overtones gives the rotational constants of the excited vibrational state, and of the lowest molecular state, which is above the minimum of the potential energy curve by the zero-point energy. The bond lengths obtained from the ground state rotational constants are approximately the mean values of the lengths in the ground state and are usually slightly larger than the equilibrium ones, and the geometry is called the r_0 -structure. The equilibrium geometry, r_e -structure, can be determined from B_e if the rovibration interaction constants α_i , defined by the equation

$$B_{v_i} = B_e - \sum \alpha_i \left(v_i + \frac{1}{2} \right) \quad [2]$$

for all the normal vibrations of the molecule are known. Typical values of a r_0 -structure are compared with a r_e -structure in **Table 2** for C_2H_2 . Since for an asymmetric top molecule there are three principal moments of inertia a maximum of three molecular parameters, bond length and angles, can be obtained. Moreover, in planar molecules only two moments of inertia are independent and in linear molecules such as acetylene the two moments of inertia are equal. Thus, determination of geometry for polyatomic molecules seems to be impossible. Isotopic substitution is the way to increase the number of independent moments of inertia so that the structure parameters of polyatomic molecules can also be inferred. In fact, molecules differing by one or more isotopes have the same r_e -structure, while the r_0 -structure is slightly different since the zero-point energy is isotope dependent. For large polyatomic molecules the determination of the r_e -structure is nearly impossible. In benzene, C_6H_6 , owing to the hexagonal symmetry, only the r_{C-H} and r_{C-C} interatomic distances are needed to determine the geometry. From the analysis of the

high-resolution IR or UV spectrum only one independent rotational constant is obtained and an isotopically substituted benzene such as C_6D_6 has to be studied to obtain the r_0 -structure. Since each isotopomer has 20 normal vibrations, and thus 20 α_i values, the analysis of 40 high-resolution bands is needed for the r_e -structure. To date, about 15 fundamental bands of C_6H_6 and C_6D_6 have been rotationally analysed.

Force Field Evaluation

Accurate *ab initio* theoretical calculations of harmonic and anharmonic force fields of molecules as large as benzene have been performed. By comparing the experimentally determined molecular constants with the calculated ones, the reliability of theoretical calculations can be assessed. All the molecular constants of COF_2 in **Table 1** can be evaluated from the theoretical anharmonic force field. For molecules such as ammonia the computed fundamental wavenumbers are within 3 cm^{-1} or better of the experiment. For anharmonic constants and centrifugal distortion constants, which are much smaller than the fundamental frequencies, the deviations are on average around 15%. The experimental determination of anharmonic constants x_{ij} that appear in the equation for the vibrational energy of a polyatomic molecule with the harmonic frequencies ω_i^0 and without degenerate vibrations:

$$G_0(v_1, v_2, v_3, \dots) = \sum_i \omega_i^0 v_i + \sum_i \sum_{j \geq i} x_{ij}^0 v_i v_j \quad [3]$$

relies on the analysis of overtone and combination bands. In **Table 1** the data under the headings $\tilde{\nu}_1$, $2\tilde{\nu}_2$ and $2\tilde{\nu}_3 + \tilde{\nu}_6$ refer to a fundamental, an overtone and a combination band, respectively. The relations between $\tilde{\nu}_0$ of **Table 1** and ω_i^0 , x_{ij}^0 are given by

$$\text{for } \tilde{\nu}_1 \quad \tilde{\nu}_0 = \omega_1^0 + x_{1,1}^0 \quad [4]$$

$$\text{for } 2\tilde{\nu}_2 \quad \tilde{\nu}_0 = 2\omega_2^0 + 4x_{2,2}^0 \quad [5]$$

$$\text{for } 2\tilde{\nu}_3 + \tilde{\nu}_6 \quad \tilde{\nu}_0 = 2\omega_3^0 + \omega_6^0 + 4x_{3,3}^0 + 2x_{3,6}^0 + x_{6,6}^0 \quad [6]$$

The assessment of the reliability of theoretical calculations is particularly important when the experiment is unable to determine some of the molecular constants, which in turn can be calculated by *ab initio* methods. In benzene, for example, there are about 300 anharmonic constants and there is little hope that all of these could be obtained experimentally. The equilibrium structure r_e is also a very important result of the theoretical calculations of molecular force field, and is to be compared with the experimental structure (see **Table 2**).

Laser Stark IR Spectroscopy

The laser Stark technique applied to IR spectroscopy is based on bringing in resonance, with a fixed frequency IR laser (such as CO₂, CO, N₂O lasers), the molecular transitions modulated via an electric field (Stark effect). From an analysis of the Stark spectra very accurate values of the electric dipole moments of molecules in the ground and excited vibrational states are obtained. Table 3 presents some of the dipole moments that have been determined.

Pressure Broadening and Pressure Shift

The pressure shift and pressure broadening of the spectral lines are primarily due to the collisions of the molecules. The study of these effects provides information on the mechanism of the molecular interactions which are mainly of dipole–dipole type. In addition, the experimental determination of the line broadening and line shift parameters is instrumental in the spectroscopic study of the atmosphere, where the absorption or emission of IR radiation takes place from regions where the pressure may change by several orders of magnitude. These effects are relatively small; for example, for the P and R branches of the ν_3 band of ¹²C¹⁶O₂ at 2350 cm⁻¹, broadened by N₂ at 296 K, broadening coefficients in the 0.066–0.089 cm⁻¹ atm⁻¹ range and shift coefficients of –0.0016–0.0037 cm⁻¹ atm⁻¹ have been reported by Devi and co-workers.

High-Resolution IR Spectroscopy of Weakly Bound Complexes

High-resolution IR spectroscopy has been used to elucidate the potential energy surfaces that govern the weak intermolecular forces between molecules, since it

provides information on the vibrationally excited region of the potential energy surface of the ground electronic state. This region controls the long- and short-range collisional dynamics of the monomers. This application was delayed until the advent of adequately sensitive detection methods and of an appropriate light source. The experimental methods are based either on direct absorption techniques of light obtained from a laser source (from a tunable diode laser or from difference frequency mixing of a dye and Ar⁺ lasers) by complexes in a cooled multiple pass gas cell or on FTIR techniques. A rotationally resolved spectrum can be recorded even though the line widths are Doppler limited or broadened by pressure or predissociation effects. From the analysis of these spectra thermodynamic properties, vibrational term values, rotational constants and bond dissociation energies may be extracted. Alternatively, supersonic molecular beam methods can be used with direct absorption laser spectroscopy or bolometric techniques. These experiments supply additional information on samples at rotational–vibrational temperatures ranging from 1–2 K for expansion from an ultracold pinhole, to 10–30 K for slit expansion. The spectroscopic techniques developed in the far-IR allow the investigation of the low-frequency intermolecular modes in complexes. Additional spectroscopic data on the large amplitude motions associated with these low frequency vibrations have been obtained from the analysis of the hot and/or combination bands observed in the mid/near-IR. Some of the complexes analysed so far are (HF)₂, (DF)₂, (HCl)₂, (CO₂)₂, (HCN)₂, (HCCH)₂, (NH₃)₂, H₂–inert gas, H₂–HF, HF–inert gas, HCl–inert gas, HF–N₂, HF–OCO, OC–HF, C₂H₂–HF, HCN–HF, HF–DF, (DF)₃. The HF and DF van der Waals complexes have attracted much attention because of their fundamental importance in the chemistry of hydrogen bonded species. Most of the spectra recorded in the near-IR are structured since the upper states are metastable with respect to vibrational (or rotational) predissociation. The main channel leading to the breakdown of the complex into its constituent sub-units is the coupling of the intramolecular mode with the dissociating, low-frequency intermolecular modes. This coupling causes a redistribution of vibrational energy in the complex that may excite the intermolecular bond up to dissociation. The excited states have to last at least for the time needed to complete an end-over-end rotation in the complex to observe a rotationally resolved structure in the spectrum. From the experimental values of FWHM line width it is possible to calculate the lifetime of the metastable state, according to

$$\tau = 1/2\pi\Delta\nu_{\text{FWHM}} \quad [7]$$

for a Lorentzian absorption line shape and a single exponential decay of the upper state population. However,

another possible contribution to the homogeneous line width comes from intramolecular vibrational relaxation (IVR). Consequently, the collision-free line width depends in principle on the combined 'predissociation/relaxation' pathway. From the analysis of high-resolution spectra a very large range of dissociation/relaxation behaviour results [$\tau > 3 \times 10^{-4}$ s for ν_1 of Ar–HF (Huang and co-workers) to $\tau \geq 10$ ps for ν_2 of the linear (HCN)₃ (Jucks and Miller)] indicating strong sensitivity to small differences in the potential energy surfaces. In many dimers a strong dependence of the line widths from specific vibrational couplings has been observed as in (HF)₂ [$\Delta\nu_1 = 13.4$ MHz, $\Delta\nu_2 = 408$ MHz (Pine and co-workers and Huang and co-workers)], HCN–HF [$\Delta\nu_1 = 2722$ MHz, $\Delta\nu_2 = 11.8$ MHz, $\Delta\nu_3 = 558$ MHz (Wofford and co-workers)]. The analysis of spectroscopic data may give insight into the coupling between intermolecular bending and stretching modes, as indicated by the results of the Coriolis analysis in the Ar–HF dimer between the ν_2 perpendicular band and the $3\nu_3$ overtone of the intermolecular stretching vibration (Lovejoy and co-workers). Additional probes of intermolecular interactions are the intensity changes and the amount of the shift of the frequency of the monomer fundamentals in complexes from their unperturbed position. From IR experiments it is possible to infer the correct equilibrium structure of a complex, i.e. that corresponding to the absolute minimum of the potential surface. Information about large amplitude motions from hot bands and combination bands analysis are also very useful to this end. Results indicate that for many complexes, i.e. CO₂, N₂O dimers, and HCN trimers, several structures, corresponding to a different minima in the potential surface, are possible and that the isomerization involves motion along intermolecular coordinates. In the case of Ar_nHF clusters a satisfactory agreement is observed between the isomer equilibrium structures predicted on the basis of pairwise additive potentials and the experimental observations (see Figure 1).

High-Resolution IR Spectroscopy of Free Radicals and Ions

IR laser spectroscopy has been employed to study free radicals and ions because of its sensitivity in the detection of compounds present in small concentrations. The spectroscopic characterization of radicals and ions is valuable in the fields of chemical kinetics, of astronomy and of plasma diagnosis. The experimental techniques used to produce unstable molecules and to record the spectra are here briefly summarized. Free radicals can be generated using the discharge-flow method, while ionic species can be obtained using a hollow-cathode discharge cell that, combined with magnetic-field modulation or

Figure 1 Equilibrium structures and energies for Ar_nHF ($n = 1-4$) predicted from pairwise additive potentials. In all cases, the lowest predicted energy structures (left) are in excellent agreement with experimental observation. Reprinted with permission of Annual Reviews from Nesbitt DJ (1994) High-resolution, direct infrared laser absorption spectroscopy in slit supersonic jet: Intermolecular forces and unimolecular vibrational dynamics in clusters. *Annual Review of Physical Chemistry* 45: 369–399.

amplitude-discharge modulation, allows the detection of the selected ionic species among neutral stable molecules. Alternatively, velocity modulation IR laser spectroscopy can be used to selectively detect ionic species among neutral ones, exploiting the characteristic Doppler shift of charged molecules. HD⁺, HeH⁺, NeH⁺, ArH⁺, HCO⁺ and HNN⁺ are some of the ions studied with this technique in the infrared and whose fundamental frequencies and molecular constants have been determined. Both radicals and ions may be generated by photolysis or photoionization of a stable precursor seeded in a rare-gas free-jet expansion. Another powerful technique with which to study ions employs a fast ion beam extracted from a plasma ion source and velocity tuned. This is merged with CO₂ laser light to induce transitions from a vibrational bound level near the dissociation limit to a repulsive electronic state or to a predissociating bound level above the dissociation limit. Most of the systems studied are diatomic, such as HD⁺, HeH⁺, He₂⁺, H₂⁺ and D₂⁺, and the information obtained

concerns the description and spectroscopy of weakly bound states, to infer deeper understanding of ion–neutral reaction dynamics and of the charge–dipole induced interaction. In addition, polyatomic unstable species have been the subject of detailed study with high-resolution IR spectroscopy, among those examined are CCH, C₃, C₄, C₉, C₁₃, NO₃, HO₂, HCCO and C₃H₃ radicals, and H₃⁺, SiH₃⁺, CH₃CNH⁺, CH₂⁺, NH₃⁺ and H₂O⁺ ions. The results of such experiments may be valuable in the field of chemical kinetics since they allow the determination of rate constants and an understanding of some aspects of the mechanism of the reaction. For example, the observation, in a hollow cathode discharge, of the ν_1 band of HOC⁺ at 3268 cm⁻¹, allowed the measurement of the abundance ratio [HCO⁺]:[HOC⁺] in the laboratory from the relative intensity of the IR high-resolution lines of the two species, using the transition dipole moments for the band of HCO⁺ (0.168 D) and HOC⁺ (0.350–D), and assuming that the rotational temperature of both ions was equal to the cell temperature (223–K) (Amano). This information was particularly valuable in studying the formation and depletion of HOC⁺ in the interstellar medium. A rate equation analysis was performed to rationalize the observed dependence of the relative intensities of HOC⁺ and HCO⁺ lines as a function of the pressures of H₂ and CO. The rate constants of some of the reactions considered in the rate equation analysis were then determined. The contribution that the analysis of the high-resolution IR spectra of such kind of molecules brings to astronomy is the determination with great accuracy of the molecular constants that allow one to search for the rotational lines in laboratory microwave spectra. These results may lead to the identification of unassigned interstellar lines. The nature and the amount of a species present in plasmas may be determined by high-resolution IR spectroscopy, as in the case of SiH₃⁺, a transient molecular ion observed and analysed in a silane discharge plasma. The ν_2 and ν_4 bands, i.e. the out-of-plane bending and the in-plane degenerate bending vibration respectively, have been recorded and analysed (Davies and Smith), taking into account the Coriolis interaction between the two vibrationally excited states.

Molecular Dynamics

Frequency domain spectroscopic techniques can be widely used to determine the homogeneous intramolecular vibrational redistribution (IVR) of energy, a phenomenon observed when molecules have enough energy to break bonds. An advantage of the frequency domain techniques is the ability to measure the rotational state-dependence of the IVR rates. Briefly, the background theory is that a single rotational state in an excited anharmonic normal-mode vibrational state (the

bright state) carries all the oscillator strength and is coupled to near-resonant vibrational dark states through perturbation terms of the Hamiltonian. As a result of this coupling the bright state oscillator strength is redistributed among the dark states. The width of the intensity distribution is a measure of the time scale of energy localization in the bright state. Thus, one goal of IVR studies is the measurement of the relaxation rates that span a wide range (50 fs to 10 ns) and are dependent on molecular structure. The two major experimental methods used for IVR studies of isolated molecules in their ground electronic state can be divided into single photon and double resonance techniques. The general requirements of these experimental methods are both high resolution and sensitivity. Quantitative IVR rates of many molecules have been determined: they span from 10⁸ to 10¹³ s⁻¹, with 3 × 10⁹ s⁻¹ being a typical value. These rates may be sufficiently slow to permit mode-selective chemistry in some systems. From a comparative analysis of the IVR rate values for the acetylenic C–H stretching for many molecules of the type (CY₃)₃XCCH (see Table 4), it appears that the lifetime and density of states are not correlated, even if the state density must be large enough to provide a bath for energy redistribution. The IVR rate is controlled by the coupling of a few dark states that interact with the bright one through low order terms of the potential energy surface, which in turn must be efficiently coupled to other non-resonant states to allow fast energy flow. Other structural aspects of IVR such as the role of large amplitude motion in IVR dynamics, the change of IVR rates by structural modification, and the degree of dependence of the IVR rates on modes are currently being studied.

Thermodynamic and Kinetic Data from High-Resolution Spectroscopic IR Studies

An example of this application is the FTIR and IR laser diode spectroscopy study of the reversible gas-phase reaction

A kinetic study has been carried out (Pagsberg et al.) by monitoring selected absorption signals of the rovibration transitions of the ν_3 and ν_5 IR bands of HONO as a function of time for different partial pressures of ammonia at a total pressure of 20 mbar. At 298 K the rate constant of the forward reaction and the equilibrium constant are $k_f = 2.2 \pm 0.2 \times 10^3 \text{ M}^{-1}\text{s}^{-1}$ and $K_c = 1.5 \pm 0.2 \times 10^5 \text{ M}^{-1}$, respectively. From the observed temperature dependence of the equilibrium constant expressed in terms of the van't Hoff equation, the values of $\Delta_r H^\circ_{298} = -49.4 \pm 3.3 \text{ kJ mol}^{-1}$ and $\Delta_r S^\circ_{298} = -111.7 \pm 4.2 \text{ J mol}^{-1} \text{ K}^{-1}$ have been derived.

The definition of high resolution in IR spectroscopy has been changing with time. In this article, the limit of high resolution is defined as 0.1 cm^{-1} . This is the full width at

half height (FWHH) of the line. In scientific language, the higher the resolution, the smaller the FWHH. In the past, grating and even prism spectrometers, which have a lower resolution than 0.1 cm^{-1} , have also been regarded as high-resolution instruments, but the development of spectroscopic instrumentation has pushed the limit of high resolution towards smaller FWHH. Nowadays, high-resolution IR spectra are generally recorded by Fourier-transform IR (FT-IR) spectrometers, or by laser spectrometers.

Michelson, in the 1880s, invented his interferometer, which was used to study the speed of light and to fix the standard metre with the wavelength of a spectral line. The use of the Michelson interferometer in spectroscopic applications was started almost 60 years later.

The first FT-IR spectrum was computed in 1949 by Peter Fellgett, who used an interferometer to measure light from celestial bodies. Transforming an interferogram into a spectrum was, however, a laborious task, and FT-IR spectroscopy for years remained the field of only a few advanced research groups, who had large computers for time-consuming Fourier transforms. The first commercial FT-IR spectrometers appeared at the end of the 1960s, when microcomputers became available. The development of the Cooley–Tukey algorithm in 1965 for a quick performance of a Fourier transform (the fast Fourier transform, FFT) was an important step for FT-IR spectroscopy. The FT-IR spectrometers of the 1960s worked with a resolution of a few wavenumbers, but they were the high-resolution technology of their own time.

There are a number of commercial high-resolution spectrometer models, and research laboratories have built their own instruments, which can achieve a resolution of 0.001 cm^{-1} , or even better.

The history of laser spectrometers is short, starting effectively at the beginning of the 1980s.

Basic Definitions

IR radiation consists of electromagnetic waves, which oscillate with a frequency of 3×10^{11} to $4 \times 10^{14} \text{ Hz}$. The corresponding wavelength range is 10^3 to $0.78 \mu\text{m}$. The infrared waves travel with the group velocity of light $c_n = c_0/n$, where c_0 is the velocity of light in a vacuum

$(2.99\,792\,458 \times 10^8 \text{ m s}^{-1})$ and n is the refractive index of the medium. IR radiation has shorter wavelength than microwaves but longer wavelength than visible light. The IR region may be subdivided into three: far-IR (10^3 to $30 \mu\text{m}$), mid-IR ($30\text{--}3 \mu\text{m}$) and near-IR ($3\text{--}0.78 \mu\text{m}$).

Generally, in spectroscopy, the interaction between the matter and the electromagnetic waves takes place via absorption or emission. The matter can absorb the electromagnetic waves with wavelength λ in the transition $E'' \rightarrow E'$ if

$$hc/\lambda = E' - E'' \quad [1]$$

where h is Planck's constant ($6.626\,076 \times 10^{-34} \text{ J s}$) and E'' and E' are lower and higher energy levels, respectively, of the atoms or the molecules. Equation [1] is a basic result of quantum physics. Emission is the inverse process, where the energy drop of the atoms or the molecules is emitted as an electromagnetic quantum hc/λ . In IR spectroscopy, generally the absorption is examined. When IR radiation penetrates through the sample material (solid, liquid or gas) the absorption is described by Beer's law

$$I(v) = I_0(v) \exp[-\beta(v)Cd] \quad [2]$$

where $I_0(v)$ and $I(v)$ are incident and transmitted intensities, respectively, $v = 1/\lambda$ is the wavenumber of radiation, $\beta(v)$ is the absorptivity, C is the concentration and d is the thickness of the sample. For a solid sample $\beta(v)C = \alpha(v)$ is the absorption coefficient. The fraction $[I_0(v) - I(v)]/I_0(v)$ is called absorption, $I(v)/I_0(v)$ transmittance, and $-\ln[I(v)/I_0(v)] = \beta(v)Cd$ absorbance. Typical curves $I_0(v)$, $I(v)$, $I(v)/I_0(v)$ and $-\ln[I(v)/I_0(v)]$ are shown in **Figure 1**. The absorbance as a function of the wavenumber v is called simply the (IR) absorption spectrum.

Fourier Transform Interferometers

Michelson Interferometer

Figure 2 illustrates a basic optical layout of the original Michelson interferometer and **Figure 3** shows schematically the ray travelling at the angle θ with the optical axis of the interferometer. If the beamsplitter divides the incident intensity I_0 into two equal parts, the output intensity is simply $I = 2I_0(1 + \cos \phi)$, with $\phi = (2\pi/\lambda) 2nd \cos \theta = 2\pi vx$, where x is the optical path difference. If $\theta = 0$, $n = 1$, and S_0 is a monochromatic point source, then $x = 2d$, and

$$I = 2I_0[1 + \cos(2\pi v 2d)] \quad [3]$$

Let us assume that S_0 has a wide-band continuous spectrum $E(v)$ as shown in **Figure 4**, and it is still a point source. Now the interference signal from the region between v and $v + dv$ is given by $dF(x, v) = 2E(v)$

Figure 1 (a) Incident (or background) spectrum $I_0(v)$ and transmitted spectrum $I(v)$. (b) Transmittance spectrum $I(v)/I_0(v)$ and absorbance spectrum $-\ln[I(v)/I_0(v)]$.

Figure 2 Optical arrangement of the Michelson interferometer. M_1 is a fixed and M_2 a moving mirror. BS is a beamsplitter and C a compensating plate. M_2' is the image of M_2 formed by BS.

$[1 + \cos(2\pi vx)]dv$, according to eqn [3]. At a given optical path difference x , the total signal is

$$F(x) = 2 \int_0^{\infty} E(v)[1 + \cos(2\pi vx)]dv \quad [4]$$

where $F(x)$ is called an interference record. By subtracting from $F(x)$ the constant term

$$\frac{1}{2}F(0) = 2 \int_0^{\infty} E(v)dv \quad [5]$$

Figure 3 Michelson interferometer produces two coherent images S' and S'' of the real source S_0 . These coherent sources generate the interference fringe pattern.

Figure 4 Wide band continuous spectrum $E(v)$ can be expressed as the sum of monochromatic infinitely narrow (dv) lines.

an interferogram is obtained:

$$I(x) = F(x) - \frac{1}{2}F(0) = 2 \int_0^{\infty} E(v) \cos(2\pi vx) dv \quad [6]$$

If it is assumed that $E(-v) = E(v)$, the computations become easier, because

$$\begin{aligned} I(x) &= \int_{-\infty}^{\infty} E(v) \cos(2\pi vx) dv \\ &= \int_{-\infty}^{\infty} E(v) \exp(i2\pi vx) dv = \mathcal{F}\{E(v)\} \end{aligned} \quad [7]$$

Hence, $I(x)$ and $E(v)$ form a Fourier transform pair, and they can be written as follows

$$\begin{aligned} I(x) &= \int_{-\infty}^{\infty} E(v) \exp(i2\pi vx) dv = \mathcal{F}\{E(v)\} \\ E(v) &= \int_{-\infty}^{\infty} I(x) \exp(-i2\pi vx) dx = \mathcal{F}^{-1}\{I(x)\} \end{aligned} \quad [8]$$

where $\mathcal{F}\{\}$ and $\mathcal{F}^{-1}\{\}$ are the Fourier transform and the inverse Fourier transform, respectively. Furthermore,

Figure 5 Typical interference record $F(x)$.

one can notice that $\mathcal{F}\{\mathcal{F}^{-1}\{I(x)\}\} = I(x)$. A typical interference record is shown in **Figure 5**.

Because in practice it is impossible to make the inverse Fourier transform $\mathcal{F}^{-1}\{I(x)\}$ of the continuous $I(x)$, one has to use the discrete Fourier transforms. Thus the interferogram $I(x)$ is sampled at the discrete points $x_j = jb$, let us say, between $x = -L$ and $x = L$. The spectrum is now given by

$$E^b(v) = b \sum_{j=-N}^{N-1} I_j \exp(-i2\pi vjb) \quad [9]$$

In practice, the discrete Fourier transform is computed by the FFT in order to minimize the needed computation time. It can be shown that

$$E^b(v) = W^b(v) * E(v) \quad [10]$$

where $*$ means convolution, and the instrumental profile due to the truncation of the interferogram at $\pm L$ and the discrete sampling is given by

$$W^b(v) = \sum_{k=-\infty}^{\infty} 2 \operatorname{sinc} \left[2\pi \left(v + \frac{k}{b} \right) \right] \quad [11]$$

And now the instrumental resolution (FWHH of the instrumental function) is given by $\Delta v = 1.207/(2L)$, where L is the maximum optical path difference (please note, a point source is assumed). Furthermore, the optimum sampling interval is given by $b = 1/(2v_{\max})$ if $E(v) = 0$ with $|v| > v_{\max}$. The optimum sampling interval guarantees there is no aliasing in the spectrum.

Collimated Beam and Extended Source in Michelson Interferometer

A practical Michelson interferometer (**Figure 6**) has an extended source, as shown in **Figure 7**, and a collimator mirror. The parabolic collimator mirror may be off-axis, as in **Figure 6**, or on-axis, as in **Figure 7**. When a denotes the area of the source, A the area of the collimator mirror, f the focal length of the collimator, $\Omega_0 = A/f^2$ the solid angle of the collimator, and $\Omega = a/f^2$ the solid angle of the source, then the signal is proportional to

$$aA/f^2 = \Omega A = a\Omega_0 \quad [12]$$

On the other hand, the optical path difference is now $x \cos \alpha \approx x[1 - \Omega'/(2\pi)]$, where $x = 2nd$ and the angle α between the optical axis and the beam varies from 0 to θ , which is the maximum of α , while Ω' is changing from 0 to Ω . Thus the total interferogram is

$$\begin{aligned} I_\Omega(x) &= \int_0^\Omega I \left[x \left(1 - \frac{\Omega'}{2\pi} \right) \right] d\Omega' \\ &= \Omega \int_{-\infty}^\infty E(v) \text{sinc} \left(\frac{vx\Omega}{2} \right) \exp \left[i2\pi vx \left(1 - \frac{\Omega}{4\pi} \right) \right] dv \end{aligned} \quad [13]$$

Figure 6 Optical layout of a practical Michelson interferometer. S_0 is a black-body source and D an IR detector; M_3 and M_4 are parabolic off-axis mirrors. M_3 and M_4 may also be normal parabolic mirrors as in **Figure 7**.

In the case of a point source,

$$\lim_{\Omega \rightarrow 0} I_\Omega(x) = \int_{-\infty}^\infty E(v) \exp(i2\pi vx) dv$$

and thus the total instrumental function can be given by

$$\begin{aligned} W_{L,\Omega}^b(v) &= W_\Omega(\mp v_0, v) * \\ &\left\{ \sum_{k=-\infty}^\infty 2 \text{sinc} \left[2\pi \left(v + \frac{k}{b} \right) L \right] \right\} \end{aligned} \quad [14]$$

This has to be used in eqn [10] instead of $W_L^b(v)$. As one can see, the instrumental line shape function [i.e. the observed line shape if $E(v) = \delta(v + v_0) + \delta(v - v_0)$] is given by

$$W_{L,\Omega}(v) = W_\Omega(v_0, v) * 2L \text{sinc}(2\pi vL) \quad [15]$$

This situation is illustrated in **Figure 8** with three different Ω values. The optimum situation is the case where the aperture broadening $W_\Omega(v_0, v)$ and the truncation broadening $2L \text{sinc}(2\pi vL)$ have approximately equal widths, i.e.

$$\frac{v_0 \Omega}{2\pi} \approx \frac{1.21}{2L} \quad [16]$$

In **Figure 8** the optimum situation is roughly in the second row. Furthermore, it can be seen that the position of the line at v_0 is given by $v_{\text{obs}} = [1 - \Omega/4\pi]v_0 = \text{constant} \times v_0$. Now, according to eqn [12], the signal is proportional to $aA/f^2 = \Omega A$, and for a given resolution, when Ω is fixed, the only parameter which has an effect on the signal is the area A of the collimator mirror. The area a of the radiation source and the focal length f of the collimator mirror can be selected freely provided that $a/f^2 = \Omega$. A similar effect can occur due to the area of the detector. As mentioned earlier, the instrumental profile plays an important role in describing the behaviour of the spectrometer. Especially in high-resolution gas-phase spectroscopy, where the instrumental profile $W_{L,\Omega}$

Figure 7 Extended IR radiation source S_0 at the focal point of the parabolic collimator mirror M.

and the real (Lorentzian) line shape have approximately equal widths, the convolution by instrumental profile changes substantially the real line shape.

Other FT Interferometers

The most difficult disadvantage of the Michelson interferometer is tilting of the moving plane mirror during a scan. It is well known that the tilting angle of the moving mirror should be less than about $\lambda/(8D)$, where λ is the wavelength of the light under study and D is the diameter of the moving mirror. Thus the driving of the mirror is very difficult with high-resolution FT-IR spectrometers. One way to solve this problem is by using a dynamic alignment system, which measures the tilting angle and tries to keep it at zero during the run. However, as the resolution increases, the probability of malfunction of the dynamic alignment system during a very long run increases.

Another solution is to use cube-corner mirrors, which consist of three mutually orthogonal plane mirrors. The

mirror system reflects any incident ray back in the opposite direction. The first very high resolution cube-corner interferometer that really worked was the Oulu interferometer in Finland. The Oulu interferometer is basically a Michelson interferometer, where the moving and the fixed mirror are cube-corners. If the corners are perfect, the tilt problem completely disappears. The only disadvantage of this type of interferometer is a shearing problem, i.e. the lateral shift of the moving cube-corner. This is the case where the moving cube-corner does not follow the optical axis of the interferometer. The lower the resolution, the more serious this disadvantage is.

A cube-corner interferometer is improved if two cube-corners are set to move back to back. Two cube-corners fixed back to back as a single moving part completely eliminates the tilting and the lateral shifts, if the cube-corners are perfect ($90^\circ \times 90^\circ \times 90^\circ$), and the corners coincide exactly. Further improvements have been made at the University of Turku, Finland, namely a super high-resolution interferometer with a resolution of $4 \times 10^{-4} \text{ cm}^{-1}$ which has the moving cube-corner pair back-to-back and the beam focus at the beamsplitter (see Figure 9). This type of interferometer is almost ideal for very high resolution IR spectrometry.

An alternative interferometer to the cube-corner is the cat's-eye interferometer, where the cube-corners are replaced by cat's-eye retroreflectors. These are components that consist of one parabolic and one spherical mirror, and reflect an incident ray back in the opposite direction. Cat's-eye interferometers are also used in high-resolution spectroscopy.

Figure 8 Total instrumental line shape function $W_{L,\Omega}(\nu)$ with three different Ω -values.

Instrumental Details of FT-IR Spectrometers

Radiation Source

Black-body radiators are used as broad band radiation sources in IR spectrometers. The only adjustable parameter of the source is the temperature; the higher the temperature, the higher the intensity. Typical temperatures are 1000–1800 K. The most commonly used sources in the mid-IR are Globars (silicon carbide), Nernst

Figure 9 Layout of the Turku high-resolution interferometer.

glowers and nichrome coils. In the far-IR below 100 cm^{-1} a high-pressure mercury lamp is quite good. Nowadays, ceramic sources have become more popular. The radiation sources may need a cooling system, like water cooling.

Beamsplitter

The beamsplitter is one of the most expensive and sensitive components of an interferometer, and must be chosen carefully.

A pellicle beamsplitter is a high tensile strength elastic membrane, which is stretched like a drumhead over a flat frame. The membrane has a high refractive index and its absorption is negligible. The most common membrane material is Mylar. An ideal beamsplitter divides the incoming intensity into two equal parts. This is, however, achieved only in a definite wavenumber region, due to the interference phenomenon in a thin film. A Mylar beamsplitter works with wavenumbers less than 1000 cm^{-1} .

In the near-IR region a beam-splitting film should be very thin. In this case it is necessary to use a low-absorption dielectric coating, which is deposited on a suitable substrate plate. A thin Ge layer deposited on a KBr substrate, with a KBr compensating plate, is a good beamsplitter in the wavenumber region $1000\text{--}4000\text{ cm}^{-1}$.

Optics

With the help of optical components the IR radiation is carried from the source through the whole spectrometer and finally to the detector. Mostly the needed accuracy is so-called geometrical accuracy. This means that the beam has to be guided to the appropriate places to within $0.1\text{--}1\text{ mm}$. However, higher accuracy is needed in order to measure the wavelength of radiation in the interferometer. It is said that there is a need for interferometric accuracy, i.e. everything should be correct within a small fraction of wavelength, say $0.01\text{--}0.1\text{ }\mu\text{m}$.

In IR spectroscopy there are only a few materials transparent enough; this means that lens optics is not usually used. Instead, the use of mirror optics is preferred and the transmission of any material is avoided. However, in certain circumstances, for convenience sake, attempts are made to use some materials, e.g. polyethylene and KBr lenses. Thus the weakest points in IR optics are, besides the beamsplitter, only the windows of the gas cell. Mirrors are often manufactured from Pyrex glass coated with metal. Gold coating has a good reflection coefficient especially in far-IR and aluminium is also quite good over the whole IR region. In IR spectrometers, plane mirrors, spherical mirrors, paraboloidal mirrors, off-axis paraboloidal mirrors, ellipsoidal mirrors, toroidal and off-axis ellipsoidal mirrors are used. In planning IR instruments one must bear in mind that a perfect imaging

takes place only in plane mirrors. All others have some kind of aberration, such as spherical aberration. These aberrations limit the performance of instruments. However, there are some special imaging situations where perfect imaging is possible, for example, a spherical mirror images perfectly only on the optical axis from the centre of curvature back to the centre of curvature. A paraboloidal mirror images from infinity to the focal point on the optical axis and the off-axis paraboloid images from infinity to the focal point, which is out of the optical axis. An ellipsoidal mirror images from one focus to another. Hence these mirrors should preferably be used, so that conditions are as near perfect as possible. This also minimizes aberrations. In IR spectroscopy it is very important that as much radiation power as possible is transmitted from the source through the whole optics to the detector.

Gas Cell

The most common sample compartment in high-resolution FT-IR spectrometers is the White cell, where the beam passes a path of $1\text{--}1000\text{ m}$. In a long-path gas cell, however, a small f/number (focal length of the mirror/diameter of the pupil) and a large size of the circular image may lead to a loss of effectivity. In the Oulu interferometer this problem was solved by an alternative multiple-path gas cell, where the images at the focal planes occur on a circle around the principal axis of the cell. The aberrations remain small in spite of a small f/number , because the successive images are relatively near to the principal axis of the optics.

Detectors

The detector of the FT-IR spectrometer is very important, because it determines the maximum possible signal-to-noise ratio (S/N ; where S = signal and N = noise) and the minimum recording time of the spectrum. IR detectors can be divided into two categories: thermal detectors and quantum detectors. Thermal detectors sense the change of temperature of a detector material due to absorption of the IR radiation. The output signal is generated in the form of a thermal electromotive force (e.g. thermocouples), the change in resistance of a conductor (bolometers) or semiconductor (thermistor bolometers), or the change in pressure of a noble gas (pneumatic detectors). Thermal detectors respond to radiation over a wide range of wavenumbers, but they are usually slow with a time constant typically from 0.001 to 0.1 s . In pyroelectric bolometers, a heat-sensing ferroelectric material changes the degree of polarization when the temperature changes due to absorption. The voltage responsivity of a pyroelectric detector at frequency f is roughly proportional to $1/f$. The most commonly used

material for the pyroelectric detector is deuterated triglycine sulfate.

In quantum detectors, IR radiation causes electrons to be excited to a higher energy level. In an n-type semiconductor, electrons in the valence band are unable to increase the conductivity. If IR radiation excites the electrons to the conduction band, they can act as current carriers. For good sensitivity, it is necessary to cool the detector. For certain detectors, such as PbS and PbSe, it may be sufficient to use a thermoelectric cooler to maintain their temperature just below ambient. Mercury cadmium telluride detectors must usually be maintained at liquid-nitrogen temperature (77 K), whereas others may require cooling to the temperature of liquid helium (4.2 K).

In the far-IR, where photon energies are very low, quantum detectors cannot be used at all. Two types of thermal detectors, each operating at liquid-helium temperatures, have been used. The first one is the germanium bolometer, often doped with a low level of copper, gallium or antimony. For increased responsivity, these detectors are cooled down to 1.5 K by pumping the detector cryostat. The second type is the InSb hot-electron detector.

The sensitivity of IR detectors is expressed by the noise equivalent power (NEP) of the detector. This NEP is the ratio of the root mean square (rms) noise voltage V_{rms} in the detector to the voltage responsivity, i.e. $\text{NEP} = V_{\text{rms}}/R$. If V_{rms} is in units of $\text{V Hz}^{-1/2}$ and R in units of V/W , then NEP is in units of $\text{W Hz}^{-1/2}$. Usually the manufacturer gives a specific detectivity D^* as a function of wavelength or wavenumber. It is defined as $D^* = \sqrt{A_D}/\text{NEP}$, where A_D is the area of the detector. Some typical D^* -curves are shown in Figure 10.

Electronics

Nowadays, IR spectrometers are computer controlled. Thus the main component of the electronics is a microprocessor, which controls all the operations of the spectrometer, collects the data, and computes, saves, displays and plots final spectra. The computer is very important to perform any kind of data treatment needed in IR spectroscopy. The other electronic parts of FT-IR spectrometers are a preamplifier and a main amplifier of the IR detector, an analogue-to-digital converter (AD converter), a set of bandpass electronic filters and power supplies. It is important that the numbers of bits and data rate of the AD converter are high enough.

Advantages of FT-IR Spectrometers

Jacquinot Advantage (Throughput Advantage)

In an interferometer the total radiation power on the detector is much higher than that in a grating instrument. In practice, the FT-IR spectrometer has an approximately 200 times larger S/N than the grating spectrometer with the same resolution and recording time. The reason is that at the optimum resolution the area of the circular aperture (the Jacquinot stop) in the FT-IR spectrometer is 200 times larger than the slit in the grating spectrometer.

Fellgett Advantage (Multiplex Advantage)

In FT-IR spectrometers all the wavenumbers ν are recorded simultaneously. Let us assume that the wavenumber

Figure 10 D^* curves for the most used IR detectors (Hamamatsu Photonics K. K., Solid State Division, 1990).

region under study consists of M resolution elements, i.e. $\nu_2 - \nu_1 = M\Delta\nu$. If the noise of a detector and an amplifier is greater than the noise of a radiation source, then the S/N is proportional to the square root of the total observation time T , i.e. $S/N \propto \sqrt{T}$. In fact $S \propto T$ and $N \propto \sqrt{T}$. In FT-IR spectrometers one observes all the times T all the M spectral elements, and thus $(S/N)_{\text{FT}} = a\sqrt{T}$; in grating spectrometers the observation time of each spectral element is only T/M , and $(S/N)_{\text{G}} = a\sqrt{T/M}$, where in both equations a denotes the same constant. And finally $(S/N)_{\text{FT}}/(S/N)_{\text{G}} = \sqrt{M}$, which is the Fellgett multiplex advantage. The Jacquinot advantage and the Fellgett advantage together give $(S/N)_{\text{FT}}/(S/N)_{\text{G}} \approx 200\sqrt{M}$ in IR.

Other Advantages

It is useful to define a K -factor as $K = \Delta\nu_{\text{true}}/\Delta\nu$, where $\Delta\nu$ is the FWHH of the instrument function $W_{\Omega L}(\nu_0, \nu)$ and $\Delta\nu_{\text{true}}$ is the FWHH of the true line shape. The optimum instrumental resolution $\Delta\nu_0 = \Delta\nu_{\text{true}}/K_0 \approx 1.21/(2L_0)$ is the case where the maximum distortion of observed lines is roughly equal to the noise of the spectrum and the optimum K -value is given by $K_0 = 2\ln[(S/N)_0]/(1.21\pi) \approx \log_{10}[(S/N)_0]$. The greatest difference between FT and grating instruments is the instrumental profiles $2L\text{sinc}(2\pi\nu L)$ (in FT) and $L'\text{sinc}^2(\pi\nu L')$ (in grating). **Table 1** shows the optimum K -values, i.e. K_0 , as a function of (S/N) , when the instrumental profile is sinc and sinc² shape. **Table 1** shows that, for example, with $(S/N) = 1000$, the optimum value K_0 for grating spectrometers is 100 times higher than that for FT-IR spectrometers. In other words, a 100 times higher resolution is needed in the case of the grating spectrometer. This is usually impossible in practice. Now, it can be concluded that the optimum instrumental resolution of the FT-IR spectrometer is the lowest

possible one or the FT-IR spectrometer measures a spectrum with the smallest possible distortions of observed lines. This is the resolution advantage of FT-IR spectrometers.

The fact that $\nu_{\text{obs}} = \text{constant} \times \nu_{\text{true}}$ is the linearity advantage of FT-IR spectrometers. It is roughly valid even though the interferometer does not work correctly, for example, in the case of phase errors in the interferogram. Furthermore, no ghost lines exist in the spectrum. However, in the grating spectra ghost lines are possible in the case of malfunction of the instrument.

Use of FT-IR Spectrometers

Performance

The instrumental resolution of high-resolution FT-IR spectrometers is, in practice, of the order of 0.001 cm^{-1} . In addition to high resolution, a good absolute accuracy of the line positions in the spectrum is maintained. A wavenumber accuracy of 10^{-9} , or even better, has been achieved.

The main field of use of high-resolution FT-IR spectrometers is molecular spectroscopy. The spectrometers are used to study the geometric structures of molecules and their behaviour in rotations and vibrations. IR spectra are effective in revealing quantum mechanical phenomena and interactions in molecules.

An example of a typical rotation-vibration band, measured with a high-resolution FT-IR spectrometer, is shown in **Figure 11**. It is the bending band ν_2 of CO_2 near 667 cm^{-1} . This spectrum was recorded by the Oulu spectrometer with an instrumental resolution of 0.002 cm^{-1} . The relative errors of the wavenumber compared to model equations are of the order of 10^{-8} . The vibration energy levels of different normal modes are sometimes very close to each other. In this case these normal modes can be coupled so that the energy levels are shifted apart. Now the observed wavenumber ν_{obs} cannot be expressed in a closed form and the rotational lines of the spectrum are shifted. With the proper quantum mechanical calculations it is possible to calculate the shifts. The high resolution and accuracy in wavenumber scale make an FT-IR spectrometer a very effective instrument to study these kinds of interactions in molecular spectra.

Calibration

In principle, the calibration of FT-IR spectrometers is performed with regard to intensity and wavenumber. However, the intensity calibration is not usually necessary because the absorbance scale is used, $-\ln(I/I_0)$, where the ratio I/I_0 automatically accomplishes the intensity calibration. The most important task in calibration is the wavenumber calibration. Usually the calibration takes place

Table 1 Optimum K -values as a function of the signal-to-noise ratio (S/N) are listed for sinc- and sinc²-type instrumental functions

S/N	<i>Sinc</i>	<i>Sinc</i> ²
10	1.21	3.59

In (b), ∇ indicates $^{12}\text{C}^{16}\text{O}_2$, $\blacktriangledown$ indicates $^{13}\text{C}^{16}\text{O}_2$ and $\diamond$ indicates $^{16}\text{O}^{12}\text{C}^{18}\text{O}$.

by simultaneous measurement of a known IR spectrum. For example, the user simply adds reference gas (known spectrum) into the sample gas under measurement. Using the known spectral lines of the reference gas it is possible to fix the wavenumber scale with an uncertainty, which is roughly the uncertainty of the reference spectral lines. The linearity advantage of FT-IR spectrometers makes it possible to reach a perfectly linear wavenumber scale. This is why only one reference line is needed, i.e. the reference laser line, to measure the optical path difference of the interferometer. The situation is completely different in grating, prism and laser spectrometers, where the wavenumber scale is more or less nonlinear with respect to the scanning parameter, such as the rotation of grating or prism. Therefore in these spectrometers it is important to use many reference lines measured simultaneously with the sample spectrum in order to achieve a good wavenumber scale.

Data Handling and Computation

Nowadays, all modern IR spectrometers are equipped with a computer. Of course, the computer calculates

absorbance $-\ln(I/I_0)$, displays the spectrum on the screen or plots the spectrum on paper, saves the spectra on disk, and so on. Modern FT-IR spectrometers are able to record very accurate spectra, where S/N is high and $|dv/v|$ is very small, typically $S/N \approx 10^5$ and $|dv/v| \approx 10^{-9}$. Also absorbance accuracy is quite high in FT-IR spectrometers. The spectra with high accuracy and high S/N include much spectral information. Often spectral information is not in a proper form in the original recorded spectra. In order to derive all the possible information from high-quality IR spectra, good data-treatment algorithms are needed. If the spectrum consists of overlapping lines, resolution enhancement methods, such as calculation of derivatives, Fourier self-deconvolution, linear prediction (or LOMEP, lineshape optimized maximum entropy linear prediction) or band fitting and factor analysis, are very useful. Other possible data treatment methods, which the users may need, are, for example, smoothing, background elimination, interference fringe pattern elimination, peak-finding algorithm, maximum-entropy method, deconvolution and multicomponent analysis methods. In modern IR spectrometers good data treatment algorithms greatly

increase the usefulness of IR spectroscopy in many applications.

Laser Spectrometers

Laser spectrometers are not very useful in IR; they have more applications in the visible region, for example, LIDAR (light detection and ranging). The reason for this is the lack of good, cheap commercial lasers for IR. Wavenumber regions, due to tuning methods, are quite narrow, and the wavenumber calibration is a problem because of the lack of good calibration lines. In some cases it is also difficult to maintain a single-mode operation of the laser. The advantages of the laser spectrometer are a very high resolution, even sub-Doppler resolution, and a good S/N of the spectra.

There are two main techniques when using lasers as IR spectrometers. The first method is simply to tune the laser wavelength over a narrow wavelength region and simultaneously detect the laser signal $I(\nu)$ transmitted through the gas cell. The second possibility is to tune the wavelength of the absorption lines by applying a magnetic (Zeeman effect) or electric (Stark effect) field to the sample gas. When the wavelength of the tuned spectral lines matches the laser wavelength, absorption takes place. Thus absorption spectra are recorded as a function of the magnetic or electric field magnitude (strength).

A diode laser spectrometer is described as a typical example of this kind of spectrometer. A simple p-n junction laser is run by applying a forward bias voltage across the junction. The parallel polished crystal faces perpendicular to the junction form the mirrors acting as a laser resonator. The coherent radiation emits at the wavenumber $\nu_k = k/(2nL)$, where k is an integer, n is the refractive index and L is the length of the resonator. The wavenumbers ν_k are called the longitudinal modes of the laser. The number of modes is typically from three to ten. Operation in IR needs the cooling of the diode laser. Tuning can be accomplished by changing the term nL , which depends on the temperature. Temperature can be fine-controlled by changing current through the junction. It is possible to tune typically 200 cm^{-1} by changing the temperature and about 2 cm^{-1} by changing the current. Thus a spectrum has to be run in parts of $1\text{--}2\text{ cm}^{-1}$ by current tuning at a constant temperature. The temperatures of the parts are selected so that the parts together

form a continuous spectrum over a desired region. Running the diode laser is very troublesome, because current tuning is needed at very many different temperatures, which makes calibration, for example, very difficult. In addition, a single-mode operation of the diode laser is needed; in other words, the integer k must be a constant. This can be performed by scanning a grating monochromator simultaneously with the laser tuning. The grating spectrometer follows the wavenumber $\nu_k = k/(2nL)$ of the mode. The change in wavenumber during tuning is measured by recording the interference fringes of a long Fabry–Perot etalon. The absolute value of the wavenumber in each part has to be fixed by calibration lines. In many applications the diode laser spectrometer solely is not sufficient. However, it is a very good instrument for looking at details over a wide region spectrum recorded by an FT-IR spectrometer. Thus the laser spectrometer is a supplementary instrument to the FT-IR spectrometer.

T_{DD}	dipolar-dephasing relaxation time

Introduction

After the first NMR experiment for obtaining high-resolution spectra of solids was carried out with the high-speed magic-angle spinning (MAS) method in 1958, the cross polarization (CP) and multipulse methods were developed as important for high-resolution solid-state NMR experiments. On the basis of these methods a CP MAS technique that combines MAS and CP has been conventionally used to obtain high-resolution solid-state NMR spectra.

In the solution state, the observable NMR chemical shift is often the average value of some preferred conformations of a molecule because of its rapid motion, but in the solid state the chemical shift is often characteristic of a specified conformation because of the highly restricted molecular motion. Thus, the chemical shifts can be used as well as the spin–lattice relaxation time (T_1), the spin–spin relaxation time (T_2) and T_1 in the rotating frame ($T_{1\rho}$) to provide information on the dynamics. At present, ^{13}C CP MAS has been widely employed to characterize the structure and dynamics of solid samples such as polymers, biopolymers, catalysts, etc. Here, we will introduce some applications of ^{13}C CP MAS NMR for the characterization of the structure and dynamics of polymers, including polypeptides and proteins and also briefly describe the applications of solid-state ^{13}C NMR spectroscopy to food materials and coals. There is also a large body of literature on high-resolution solid-state ^{13}C NMR spectroscopy of small molecules, although the methods used are largely the same as those given here.

Synthetic Polymers

Polymer materials are almost always used as solids. It is well known that the properties of polymers depend on

their structure and dynamics. Therefore, to design new polymer materials, it is necessary to understand more deeply their property–structure relationships. The X-ray diffraction method has provided the structure of polymers which have high crystallinity. However, most polymers have low crystallinity and so structural information about the non-crystalline region, which is the major component, cannot be obtained by X-ray studies. Therefore, X-ray diffraction is of limited use in the structural analysis for such systems. Chain segments in the non-crystalline region are sometimes in a mobile state and so the X-ray diffraction method provides no structural or dynamic information. On the other hand, solid-state NMR provides knowledge of the structure and dynamics of a sample irrespective of whether the region studied is crystalline or non-crystalline.

Polyethylene

Polyethylene (PE) is a typical plastic. The polymer chain exhibits a *trans* and two kinds of *gauche* conformations, between which the energy difference is small and so the polymer takes various configurations under different conditions. PE has two kinds of crystal forms, as determined by several spectroscopic methods such as NMR, X-ray diffraction, electron diffraction, IR and neutron diffraction methods. One form is the orthorhombic form which occurs under normal conditions and another is the monoclinic form which occurs under high pressure or drawn conditions. In both crystal forms the conformation is the all-*trans* zigzag conformation, but the chain arrangements are different from each other. The all-*trans* zigzag planes in the orthorhombic form are perpendicular to each other, and in the monoclinic form they are parallel. Further, there also exist non-crystalline and interfacial phases. Their existence strongly affects the physical properties of the polymer. Therefore, it is very important to analyse the detailed structure of PE in the solid state to understand its physical properties.

Figure 1 shows ^{13}C CP MAS NMR spectra of single crystal PE (SC-PE), melt-quenched PE (MQ-PE) and drawn PE (DR-PE). Only one sharp peak (33.0 ppm) appears in the SC-PE spectrum. However, MQ-PE and DR-PE have two and three peaks, respectively. This means that MQ-PE and DR-PE have at least two or three kinds of magnetically inequivalent carbon atoms. These

Figure 1 ^{13}C CP MAS NMR spectra of polyethylene. (a) SC-, (b) MQ- and (c) DR-PE. Parts (a) and (b) reproduced with permission of Elsevier Science from Ando I, Sorita T, Yamanobe T, et al. (1985) *Polymer* 26: 11 864. Part (c) reproduced with permission of Elsevier Science from Van der Hart DL and Khoury F (1984) *Polymer* 25: 1589.

peaks have been assigned by T_1 measurements; peak a (31 ppm) comes from the non-crystalline region, which is a mobile state, and peak I (33 ppm) from the crystalline region, which is in an immobile state. Further, the high-frequency peak of DR-PE (35.0 ppm) is assigned to the methylene carbons in the monoclinic crystal region. These assignments were justified by quantum chemical shielding calculations with the tight-binding (TB) sum-over-states (SOS) method. A peak from the interfacial region between the crystal and non-crystalline regions has also been reported.

The crystal structure of PE has been proposed from models such as sharp-fold, switch-board and loose-loops models as shown in **Figure 2a–c**. To obtain detailed information on the fold structure, SC- and MQ-PE have been studied by high-resolution solid-state ^{13}C NMR. This study reveals that SC- and MQ-PE take the adjacent re-entry type of macroconformation in addition to loose and long loops in the fold surface, as shown in **Figure 3**. The number of carbon atoms in the *trans* zigzag chain from one fold to the next is estimated to be ~ 100 , which leads to an estimate of the stem length of about 125 Å. Its magnitude is consistent with the crystal thickness (120–150 Å) measured directly for PE single crystals by electron microscopy.

The physical properties of polymers in the solid state are strongly affected by temperature. Variable-temperature (VT) NMR techniques should provide useful information on the structural and dynamic aspects of polymers in the solid state. The advantage of VT solid-state NMR techniques is that the temperature

Figure 3 Schematic illustration of the folded chain conformation form of melt-quenched polyethylene. (a) *trans* zigzag, (b) sharp-fold and (c) loose and long loop. Reproduced with permission of Elsevier Science from Ando I, Sorita T, Yamanobe T, et al. (1985) *Polymer* 26: 1864.

dependence of the conformation and molecular motion can be studied by observing the chemical shift. The structure of ultrahigh relative molecular weight PE (UHRMW-PE) has been investigated in the solid state by

VT ^{13}C CP MAS NMR. The ^{13}C NMR spectrum of UHRMW-PE at room temperature has two peaks (the low and high frequency peaks are designated by A and I, respectively) as shown in **Figure 4**. Their chemical shifts agree with those for the melt-crystallized PE (MC-PE), and so peaks I and A have been assigned to the crystalline region with the *trans* zigzag conformation and to the non-crystalline region, respectively. When the temperature is decreased, peak A shifts to low frequency but peak I shifts to high frequency. The ^{13}C chemical shift behaviour for peak A of UHRMW-PE is similar to that of MQ-PE. At -108°C , the molecular motion is frozen and the chemical shift for peak A is about 32 ppm. Therefore, peak A is due to the methylene carbons in the *trans* conformation in the non-crystalline region since in the

Figure 4 ^{13}C CP MAS NMR spectra of ultrahigh relative molecular mass polyethylene as a function of temperature. Reproduced with permission of John Wiley & Sons from Akiyama (1990) *Journal of Polymer Science, Part B: Polymer Physics* 28: 587.

frozen state a methylene carbon in the *gauche* conformation should appear at about 27 ppm because of the γ -*gauche* effect. On the other hand, the ^{13}C chemical shift of peak I shifts to low frequency, which is opposite to the case of MQ-PE, with decreasing temperature. At -108°C , the chemical shift is about 32 ppm, and peaks A and I coalesce. It is difficult to conclude that the cause for the low frequency shift of peak I is a change of structure in going from the orthorhombic form to a different crystal structure. It is known that the ^{13}C shifts of methylene carbons in the orthorhombic, triclinic and monoclinic forms are about 33, 34 and 35 ppm, respectively. From these results, the ^{13}C shift of 32 ppm at -108°C indicates that the crystalline structure is different from other crystal structures found at room temperature. The other possibility for the low frequency shift is a distortion of the orthorhombic form.

The relaxation parameters, T_1 , dipolar-dephasing relaxation times (T_{DD}), etc. can provide useful information on the dynamics of polymer motion in the solid state and to monitor solid-state polymer phase transitions.

The non-crystalline region of two kinds of PE samples, using single ^{13}C -labelled solution-crystallized PE (PE-SL) and single ^{13}C -labelled melt quenched PE (MQ-PE-SL), has been studied by VT ^{13}C CP MAS NMR. The dynamics of the non-crystalline region have been discussed by measuring ^{13}C T_1 and T_{DD} from -120 to 44°C . Each of these spectra consists of three peaks, corresponding to an orthorhombic crystalline peak at 33.0 ppm, a monoclinic crystalline peak at 34.4 ppm (a small shoulder on the left-hand side of the orthorhombic peak) and a non-crystalline peak which appears at 30.8–31.3 ppm. The ^{13}C T_1 data of these samples over a wide range of temperature, obtained using the inversion-recovery method with the pulse saturation transfer (PST) pulse sequence, are given. The PST pulse sequence enhances the intensity of mobile methylene carbons. The T_1 values for samples PE-SL and MQ-PE-SL are plotted against the inverse of the absolute temperature ($1/T$) in **Figure 5a**. It has been suggested previously that local molecular motion in the non-crystalline region of PE is independent of the degree of crystallinity, higher-order structures or morphologies. However, these suggestions are not supported by the experimental results of PE-SL and MQ-PE-SL for two reasons: one is the difference in T_1 values and the other is the large difference in the temperature of the T_1 minimum of the non-crystalline region between PE-SL and MQ-PE-SL, as shown in **Figure 5a**. These facts show that local molecular motions in the non-crystalline regions of the PE-SL sample are more constrained than that of MQ-PE-SL. To study whether the dynamic behaviour of the two kinds of non-crystalline region is also different on the T_2 time-scale, T_{DD} values of samples of PE-SL and MQ-PE-SL were measured over a wide temperature range. The relative

Figure 5 (a) Plots of non-crystalline ^{13}C spin-lattice relaxation times: T_1 of PE-SL samples (●) and MQ-PE-SL (○) versus the reciprocal absolute temperature. (b) Intensity of non-crystalline peaks of a sample of PE-SL and MQ-PE-SL versus delay time τ . The peak intensity was obtained from computer simulation of the ^{13}C partially relaxed dipolar-dephasing NMR spectra. Reproduced with permission of John Wiley & Sons from Chen Q, Yamada T, Kurosu H, Ando I, Shioino T, and Doi Y (1992) *Journal of Polymer Science, Part B: Polymer Physics* 30: 591.

intensity of the non-crystalline peak obtained from computer simulation was plotted against the delay time τ in **Figure 5b**. It can be clearly seen that the non-crystalline peak of the sample of PE-SL relaxes more quickly than that of the MQ-PE-SL sample. The value of T_{DD} depends on molecular motion, carbon-proton dipolar interactions, MAS rate and spin diffusion. Fundamentally, it can be said that the dipolar dephasing time in the non-crystalline region becomes a measure of molecular motion because of the high mobility. Therefore, the longer T_{DD} value of MQ-PE-SL, compared with that of PE-SL obviously suggests that the carbon-proton dipolar interaction is partially averaged by molecular motion on the T_2 time-scale.

Poly(vinyl alcohol)

Poly(vinyl alcohol) (PVA) is used as a high-performance fibre and as a barrier material against oxygen. Detailed information about the structure and molecular motion is needed in order to develop and design this material. The ^{13}C CPMAS NMR spectra of PVA have been measured at room temperature. The methine carbon resonance split into three peaks in the CP MAS NMR spectrum. In the case of solution state NMR, the three methine carbon resonances and relative intensities correspond to the triad tacticity. However, the chemical shifts of the three methine carbons in the solid state are about 77, 71 and 65 ppm (**Figure 6**) and the relative intensities are not consistent with the triad tacticity in solution. The chemical shifts of two high-frequency peaks move significantly to higher frequencies in the solid state. These peaks, on the basis of the formation of intramolecular

Figure 6 ^{13}C CP-MAS spectra of poly(vinyl alcohol) at room temperature. (a) syndiotactic, (b) isotactic and (c) atactic. Line spectra represent the ^{13}C spectra in $\text{DMSO}-d_6$ solution at 353 K. Reproduced with permission of American Chemical Society from Terao T, Maeda S, and Saika A (1983) *Macromolecules* 16: 1535.

hydrogen bonds, have been assigned as follows. The highest frequency peak of the methine carbon is assigned to the *mm* triad with two intramolecular hydrogen bonds, the second highest one is assigned to the *mm* and *mr* triad

with one intramolecular hydrogen bond and the other peak is assigned to the *mm*, *mr* and *rr* triads with no intramolecular hydrogen bonds.

Most recently, the ^{13}C CP MAS NMR spectra of PVA gels were measured to clarify the structure of their immobile component. In the ^{13}C CP MAS NMR spectra, the three carbon peaks were clearly observed, and originate from the formation of strong intermolecular or intramolecular hydrogen bonds between OH groups as seen for PVA in the solid state as mentioned above. Further, the molecular motion of immobile and mobile regions of PVA gel through the observation of ^{13}C T_1 has been studied.

Polyoxymethylene

The molecular motion of polyoxymethylene (POM), which is the first member of the polyether series, has been investigated using the two-dimensional (2D) exchange experiment. The observed and calculated 2D exchange spectra of POM are shown in Figures 7a and 7b, respectively. The spectrum observed at 252 K shows only diagonal signals and thus no molecular motion occurred during the mixing time. However, if molecular motion occurred during the mixing time, the spectrum would show steric effects as shown in Figure 7c. The calculations were performed by using the model of helical jump motions, assuming a one-dimensional random walk in continuous time and elementary processes of 200° jumps. Thus, at $T=360\text{ K}$ the subspectra can be identified for the discrete steps of a given CH_2 group that POM experiences, as the helix rotates.

Fluoropolymers

Fluoropolymers have excellent properties and have been widely used for various purposes under severe conditions. Although high-resolution solid-state NMR is a powerful tool with which to elucidate structures and dynamics of polymers in the solid state as mentioned above, the ^{13}C CP MAS experiment often fails to provide detailed information on the structures of fluoropolymers because their spectra give rise to broad peaks. This is mainly due to two dominant factors, namely large dipolar coupling and the shielding anisotropy of fluorine nuclei. Although the high-speed magic-angle spinning (HS MAS) method leads to a significant reduction in such broadening for ^{19}F NMR in the solid state and has been used to characterize fluoropolymers, only a few ^{13}C solid-state NMR experiments have been reported. The simultaneous application of proton and fluorine decoupling drastically reduces line broadening caused by ^1H - ^{13}C and ^{19}F - ^{13}C dipolar interactions. The two kinds of poly(vinylidene fluoride), non-polar α phase and polar β phase, have been characterized by means of solid-state triple-resonance spectroscopy. There was a small

Figure 7 (a) Pure absorption-mode 2D exchange spectra of isotactic POM at $T=360\text{ K}$ and mixing time $t_m=2\text{ s}$, (b) theoretical spectrum of (A) with $x=2\omega$, $t_m=2.5\text{ s}$ and (c) $T=252\text{ K}$ and $t_m=1\text{ s}$. difference ($\sim 4\text{ ppm}$) in the chemical shift positions for these distinct crystalline modifications.

Blend Polymers

Multicomponent organic polymer materials such as polymer blends are important in industry. Their macroscopic properties are determined not only by the molecular properties of the individual polymers, but also by the miscibility, morphology and structure of the interfaces between the polymers. Solid-state NMR is a useful tool to study the microscopic structure of heterogeneous polymer materials.

The miscibility of PMMA and poly(vinylidene fluoride) (PVDF) has been established by various methods. Both ^{19}F - ^{13}C and ^{19}F - ^1H CP and molecular miscibility in blends of PVDF and isotactic, syndiotactic and atactic PMMAs were investigated by triple resonance ^1H , ^{19}F , ^{13}C solid-state CP MAS NMR. The fraction of nonmixed PMMA was determined for these blends, and it was found that this fraction was smaller for isotactic than for atactic and syndiotactic PMMAs.

A study of the polymer blends of poly(vinyl phenol) and poly(methyl acrylate) using 2D ^{13}C - ^1H correlation

NMR has been reported. From the spectrum, a direct interaction between the hydroxyl hydrogen of poly(vinyl phenol) and the carbonyl carbon of poly(methyl acrylate) can be deduced. The miscibility in annealed 50:50 blends of a random, copolyester Vectra-A, containing 73% *p*-hydroxybenzoic acid and 27% hydroxynaphthoic acid, and poly(ethylene terephthalate) (PET), has been discussed by using a standard 2D exchange experiment. The small cross peaks between the peaks of aliphatic PET and those of quaternary Vectra-A carbons indicated intimate mixing.

Biopolymers

In the solution state, the NMR chemical shifts of biopolymers with internal rotations are often averaged values for all internal rotations because of rapid interconversion by rotation about peptide bonds. In the solid state, however, chemical shifts are often characteristic of specific conformations because of highly restricted rotation about the peptide bonds. The NMR chemical shift is affected by a change in the electronic state arising from the conformational change. NMR chemical shifts in the solid state, therefore, provide useful information about the electronic state and conformation of a biopolymer with fixed structure, especially membrane-bound polymers. Several studies of typical synthetic polypeptides and membrane proteins using high-resolution ^{13}C NMR in the solid state are given here.

Synthetic Polypeptides

Synthetic polypeptides consist of repeating sequences of certain amino acids and their structures are not as complicated as those of proteins. For this reason, synthetic polypeptides are sometimes used as model compounds for proteins. Their preferred conformations are classified as α helix, β sheet, ω helix and so on. High-resolution solid-state ^{13}C NMR spectroscopy has proved to be a very powerful tool for determining the structure of polypeptides in the crystalline state. For example, ^{13}C CP MAS NMR spectra of solid poly(L-alanine) ($[\text{Ala}]_n$) show the $\text{C}\alpha$, $\text{C}\beta$ and $\text{C}=\text{O}$ carbon signals to be well resolved between the α helix and β sheet forms. The chemical shifts of the $\text{C}\alpha$ and $\text{C}=\text{O}$ carbons of the α helix are displaced significantly to high frequency by 4.2 and 4.6 ppm, respectively, relative to those of the β sheet form, while the shift of the $\text{C}\beta$ carbon of the α helix is displaced to low frequency by about 5 ppm with respect to that of the β sheet. For this reason, the value of the ^{13}C shift can be used to describe the local conformation. In addition, the ^{13}C shifts of randomly coiled $[\text{Ala}]_n$ in trifluoroacetic acid solution have values between those of the α helix and β sheet forms. The absolute ^{13}C shifts of the $\text{C}\alpha$ and $\text{C}\beta$ carbons are affected by the chemical

structure of the individual amino acid residues and can be used effectively for conformational studies of particular amino acid residues in polypeptides and proteins. On the other hand, the $\text{C}=\text{O}$ shifts do not seem to be affected by residue structure and can be used for diagnosing the main chain conformation.

Recently, the relation between the amide proton shift and the conformation of synthetic polypeptides has been studied in the solid state using ^1H combined rotation and multipulse spectroscopy (CRAMPS). It has been determined that the amide chemical shifts of a synthetic polypeptide are 8.0–8.1 ppm for the α helix and 8.6–9.1 ppm for the β sheet. It was shown that high-resolution solid-state ^1H NMR such as CRAMPS is also a useful tool for studying the molecular structure of polypeptides in addition to high-resolution solid-state ^{13}C NMR.

Poly(β -benzyl-L-aspartate) (PBLA) in the solid state adopts various conformations such as a right-handed $\alpha(\alpha_R)$ helix, a left-handed $\alpha(\alpha_L)$ helix, a left-handed $\omega(\omega_L)$ helix and a β sheet form, depending on the temperature. VT ^{13}C CP MAS NMR spectra of PBLA are shown in **Figure 8**. From this, it is clear that the conformational changes such as α_R helix $\rightarrow \omega_L$ helix $\rightarrow \beta$ sheet occur with increasing temperature.

Poly(γ -*n*-octadecyl-L-glutamate) (POLG) forms a crystalline phase composed of paraffin-like crystallites together with the α helical main chain, packing into a characteristic layer structure. The polymer forms thermotropic cholesteric liquid crystals by the melting of the side-chain crystallites. The conformational changes of POLG have been studied extensively by high-resolution solid-state NMR. **Figure 9** shows the ^{13}C CP MAS NMR spectrum of POLG at room temperature together with the assignment of peaks. At room temperature, ^{13}C shift values of the $\text{C}=\text{O}$ and $\text{C}\alpha$ carbons are 176.0 and 57.6 ppm, respectively. These values show that the main chain takes an α helix conformation. On the other hand, the interior CH_2 signal splits into two peaks. From reference data of *n*-alkanes and polyethylene, it is seen that the peak at 33.4 ppm is the carbon signal in the all-*trans* zig-zag conformation in a crystalline state and the peak at 30.6 ppm is the carbon signal in the non-crystalline phase or the liquid phase.

Figure 10 shows the VT ^{13}C CP MAS NMR spectra of POLG over the temperature range -40 to 230°C . The *n*-alkyl peaks change noticeably as the temperature is increased. The peak of the carbon signal in the non-crystalline state disappears above 50°C and the intensity of the interior CH_2 carbon in the non-crystalline state increases noticeably. This is due to the melting of side-chain crystallites. On the other hand, ^{13}C shift values of the $\text{C}=\text{O}$ and $\text{C}\alpha$ carbons are independent of temperature. It is shown that the main chain takes on a right-handed α helix conformation within the temperature range -40 to 230°C .

For samples which show a variation in molecular motion with temperature it is useful to measure the T_1 value using both the inversion–recovery method with the PST pulse sequence and Torchia's pulse sequence, depending on the type and rate of molecular motions. The molecular motions of POLG have been investigated within the temperature range -40 to 230°C , using both methods. **Figure 11** shows the temperature dependence of T_1 for some typical carbons. According to the BPP theory, T_1 decreases, passes through a minimum (at a

correlation time: τ_c) and increases again when molecular motion increases, i.e. temperature is increased. The ^{13}C T_1 values of POLG are very short in spite of the fact that, as seen from the chemical shifts, the n -alkyl side-chains of POLG are in the crystalline state in the temperature range -40 to 40°C . If the n -alkyl side-chains are in the crystalline state, the ^{13}C T_1 values must be very long by analogy with the n -alkane data. However, the ^{13}C T_1 values for individual carbons of the n -alkyl side-chains are very short and very close to the T_1 values of

Figure 10 VT ^{13}C CP MAS NMR spectra of POLG as a function of temperature. Reproduced with permission of Elsevier Science from Katoh E, Kurosu H, and Ando I (1994) *Journal of Molecular Structure* 318: 123.

n-alkanes in the rotator phase; in addition, the ^{13}C T_1 values for individual carbons of *n*-alkyl side-chains are almost the same as for *n*-alkanes in the rotator phase. From these results, it can be said that the *n*-alkyl side-chains of POLG are in a phase similar to the rotator phase, in which they undergo fast rotation such as libration, along the *trans* zigzag chain axis. The effect of the transitions at 45°, 60° and between 90° and 110°C on the individual carbon of the side-chains has also been investigated. The transition at 45°C comes from the melting of the side-chains, while other changes come from changes of the liquid crystalline phase, which has also been proved by other means.

It has been demonstrated that the introduction of fluorine atoms into polymers induces new physical properties by changes in intra- and intermolecular interactions. Poly(γ -glutamate)s with *n*-fluoroalkyl side-chains have been studied using high-resolution solid-state NMR. From the experimental results, it was found that the conformation of the main chain depends on the carbon number of the *n*-fluoroalkyl side-chains. The main chain of poly(γ -alkyl-L-glutamate) with short *n*-fluoroalkyl side-chains takes the helix form and the

poly(γ -alkyl-L-glutamate) with long *n*-fluoroalkyl side-chains takes the β sheet form. These conformational behaviours in the solid state are different from that of poly(γ -alkyl-L-glutamate) without *n*-fluoroalkyl side-chains.

Fibrous Proteins

Since fibrous proteins generally have periodical amino acid sequences and higher-order structure, the clarification of their fine structure in the solid state becomes very important not only when discussing the physical and chemical properties, but when obtaining information about the molecular design of synthetic polypeptides. The conformation-dependent ^{13}C CP MAS NMR chemical shifts are particularly useful for the determination of the conformational features of fibrous proteins such as silk fibroin, collagen and wool keratin. For example, the conformational transition of *S*-carboxymethyl keratin that has low-sulfur fractions (SCMK low-sulfur) has been estimated. For SCMK low-sulfur heated at 200°C for 3 hr under vacuum, the ^{13}C MAS NMR spectrum shows that each signal becomes broader than

Figure 11 Temperature dependence of ^{13}C T_1 for individual carbons of POLG. (a) CH_3 , (b) $\alpha\text{-CH}_2$ and (c) int-CH_2 (a and b indicate transition temperatures; m indicates melting point). For T_1 measurement in the temperature range -40 to 50 $^{\circ}\text{C}$ Torchia's pulse sequence was used, and in the temperature range 50 to 230 $^{\circ}\text{C}$, the inversion–recovery pulse sequence was used. Reproduced with permission of Elsevier Science from Katoh E, Kurosu H, Kuroki S, and Ando I (1994) *Journal of Molecular Structure* 326: 145.

those of other treated specimens. This indicates the existence of various conformations and/or different microenvironments in the heated SCMK low-sulfur. Thus, it can be said that the random coil form appears by heating. On the other hand, from X-ray diffraction, the α helix form completely vanishes in SCMK low-sulfur under the same conditions. The difference between the results from X-ray diffraction and NMR spectroscopy suggests that only the packing of the ordered structure (α helix form) in SCMK low-sulfur is disrupted by heating, while the secondary structure is retained.

Membrane Proteins

Membranes provide a vital interface between a biological organism and its environment. Furthermore, they provide a means for the formation of compartments within a cell. In every sense, they are vital to living systems. Indeed, since membranes and membrane proteins cannot easily be crystallized, NMR spectroscopy is a particularly powerful method for probing their structure and function. $[1\text{-}^{13}\text{C}]\text{Ala}$, $[3\text{-}^{13}\text{C}]\text{Ala}$ and $[1\text{-}^{13}\text{C}]\text{Val}$ selected

labelling of bacteriorhodopsin (bR) is a very convenient probe for conformation and dynamics studies. **Figure 12** shows the ^{13}C CP MAS NMR spectra of $[3\text{-}^{13}\text{C}]\text{Ala}$ and $[1\text{-}^{13}\text{C}]\text{Val}$ bR. The peaks of $[3\text{-}^{13}\text{C}]\text{Ala}$ bR have been assigned to the α_{II} helix form at 16.3 ppm (60%), α_{I} helix form at 14.9 ppm (20%) and the loops at 17.2 ppm (20%), taking a variety of turn structures. Further, from the VT CP MAS ^{13}C NMR spectrum of $[3\text{-}^{13}\text{C}]\text{Ala}$ -labelled bR, well-resolved signals were observed at both ambient temperature and -20 $^{\circ}\text{C}$ but were broadened considerably at temperatures below -40 $^{\circ}\text{C}$. This situation was interpreted as showing that interconversion between several slightly different conformations is taking place. It was found that the exchange process was strongly influenced by the manner of organization of the lipid bilayers, and depended upon the presence or absence of cations responsible for electric shielding of the negative charge at the polar head groups. The secondary structures of $[3\text{-}^{13}\text{C}]\text{Ala}$ -labelled bR were not always identical at temperatures between ambient and lower temperatures, since the ^{13}C shifts and relative peak intensities from purple membrane preparations containing these salts

Figure 12 ^{13}C CP MAS NMR spectra of (a) [3- ^{13}C] Ala bR and (b) [1- ^{13}C]Val bR in the purple membranes. (*) signals of ^{13}C -labelled lipids. Reproduced with permission of Elsevier Science from Tuzi S, Naito A, and Saito H (1994) *Biochemistry* 33: 15 046.

changed with temperature in the range -110 to 23°C . In particular, some residues involving Ala residues at the α_{II} helix and loop region were converted at temperatures below -60°C into a conformation of bR involving a α_1 helix.

The rotational resonance (RR) method is one of several solid-state NMR approaches that have been developed for determining weak dipolar couplings under conditions of MAS. To measure heteronuclear dipolar interactions, such as between ^{13}C and ^{15}N , rotational echo double resonance (REDOR) and transferred-echo double resonance (TEDOR) NMR have been developed. The measurement of weak dipolar couplings in MAS experiments using any of these methods greatly enhances solid-state NMR studies of biological systems since the dipolar couplings are directly related to internuclear distances which in turn provide constraints for the determination of molecular structure.

The interatomic distances in a crystalline specimen of the ^{13}C , ^{15}N doubly labelled simple peptide, N-acetyl-Pro-Gly-Phe, evaluated from REDOR data were compared with those from X-ray diffraction studies and found to justify such a novel approach. The REDOR-derived

conformation of this peptide was β turn type I, consistent with the X-ray diffraction study. The maximum deviations of the distances determined by NMR and X-ray diffraction is $0.08\text{ \AA}$ despite the complete neglect of the dipolar interactions with the labelled nuclei of neighbouring molecules and natural abundance nuclei. The precision and accuracy given by ^{13}C REDOR experiments are of the order of $0.05\text{ \AA}$. Distinction between the two types of β turn forms, including the β turn type II, found in the monoclinic crystal of this peptide (whose interatomic distances are different by about $0.57\text{ \AA}$) is made possible only by very accurate REDOR measurement.

More recently, it is the ability of solid-state NMR to give completely resolved spectra of immobile proteins that has enabled the structures of larger membrane proteins to be determined in the definitive environment of lipid bilayers. Further, high-resolution solid-state ^{13}C NMR spectra of the [3- ^{13}C]Ala-labelled fragment of bR incorporated into dimyristoylphosphatidylcholine bilayers have been recorded. This approach has proved useful for the assignment of peaks as well as dynamic features of the transmembrane helices in lipid bilayers.

Coals and Coal Products

The complete molecular structure of coal is one of the unsolved secrets of nature. Of the various analytical methods available, NMR spectroscopy has proved to be of special importance in coal research. Solid-state NMR techniques allow the structure of coal and coal products to be investigated in a direct and nondestructive way.

The accuracy of aromaticity measurements on coals by CP MAS ^{13}C NMR, together with additional problems posed by high-field measurements and spectral editing, and some emerging techniques, have been discussed. It is suggested that a combination of low field, single-pulse excitation with long relaxation delays and the use of a suitable reagent to quench paramagnetic centres is the most satisfactory, albeit time consuming, recipe for obtaining reasonably reliable results on unknown samples.

One particular coal, Illinois No. 6, has been measured by 2D ^{13}C - ^1H chemical shift correlation spectroscopy. A variant of dipolar shift correlation spectroscopy has been described and this is very convenient for determining the relative amounts of methylene, methine and methyl or non-protonated carbons in a complex mixture such as coal.

Foods

It has long been recognized that NMR can be of use to the food scientist and food processor. However, it is only relatively recently that there has been a consistent and widespread growth of the use of NMR. One reason for this is the development of new solid-state NMR methods.

Work on starch provides an excellent example of the information obtainable from solid-state NMR. Native starch granules have crystalline and non-crystalline regions. The crystalline regions are made up of an ordered arrangement of polymer chains in the form of double helices, whereas the amorphous regions contain single chains. The two polymorphs of starch, A (from cereals) and B (from tubers), have different packing arrangements of the double helices. The CP MAS NMR spectra of

various native starches clearly demonstrate distinguishable crystalline and amorphous regions.

^{13}C CP MAS and single-pulse (SP) MAS spectra have been obtained for galactomannans and glucomannans as powders, hydrates or gels. Comparison of CP and SP experiments on galactomannan gels did not reveal any chemical shift changes, suggesting that the conformations of mobile and rigid segments are similar. CP MAS experiments have been performed on purified carrageenans and agaroses and on the seaweeds which are the source of these materials. Although the lines were broad, characterization of the intact algae was possible and various substituents were identified.

Symbols

$\hbar$	Planck's constant/ 2π
I	nuclear spin quantum number
r	distance between spins
T_1	relaxation time
Δ	Bloch–Siegert shift
γ	gyromagnetic ratio
μ_0	permittivity of vacuum
ν_r	spinning frequency
τ_c	correlation time
θ	angle between internuclear vector and magnetic field direction
ω	Larmor frequency

Introduction

Hydrogen (^1H) and fluorine (^{19}F) possess the highest magnetic moments amongst all isotopes in the periodic table (besides the radioactive tritium, ^3H), which gives them the greatest NMR sensitivity and strongest dipolar couplings. Their spin of $I = \frac{1}{2}$ makes them well suited for structural investigations, and ^1H is indeed the most widely used nucleus in solution-state NMR. In the solid state, however, the very advantage of strong dipolar interactions, conveying long-range distance information, turns to a disadvantage when rapid spin diffusion occurs between nuclei in an extensively coupled network. The high abundance of ^1H in organic compounds thus leads to substantial line-broadening, and the same happens to ^{19}F in a perfluorinated or protonated environment. Several different line-narrowing approaches have been developed to achieve high resolution, namely magic-angle spinning (MAS), multiple-pulse sequences, a combination of both (CRAMPS), or the use of uniaxially oriented samples. Some important experiments will be illustrated here that are applicable to both ^1H and ^{19}F for determining chemical shift values, segmental mobilities, and through-space correlations. Depending on the material, both nuclei have been fruitfully applied in the analysis of inorganic crystals, organic solids, glasses, polymers, liquid crystals and biological systems. The extensive literature on broadband NMR studies of these systems will not be considered here.

The high-frequency channel of a standard solid-state NMR spectrometer tends to be optimized for ^1H , especially when ^1H -decoupling is required for observing ^{13}C and other low-band nuclei. For ^{19}F NMR experiments it is necessary to re-tune the transmitters, amplifiers and probes, and some extra hardware may need to be implemented when ^{19}F and ^1H are to be used simultaneously. The areas of ^1H and ^{19}F NMR have thus been pursued by different groups and with different objectives. If any general trends are to be identified, solid-state ^1H NMR appears to be moving towards higher resolution by working at high magnetic field strengths (currently ca. 20 T), by applying high MAS speeds (beyond 35 kHz), by making use of multidimensional experiments (HETCOR, multiquantum), and with an awareness of the physical limitations to the inherent spectral line widths. Concerning the solid-state ^{19}F NMR analysis of (per-) fluorinated materials, an observation of ^{19}F is often preferred over the otherwise very popular ^{13}C , because in these systems the ^{13}C resonances are strongly broadened and not so readily decoupled from the ^{19}F spins. With yet another motivation to study dilute ^{19}F -labels in a protonated environment, namely in organic and biological systems, many ^{19}F NMR experiments can be realized under efficient ^1H -decoupling that are analogous to ^{13}C NMR.

Properties of the Nuclei

The nuclear spin properties of ^1H and ^{19}F are summarized and compared in **Table 1**. The high gyromagnetic ratios γ provide both isotopes with a much higher sensitivity than ^2H (1% of ^1H), ^{13}C (1.6%) or ^{15}N (0.1%), to name a few, and these factors are further enhanced by the respective natural abundances. The homo- and heteronuclear dipolar Hamiltonian also depends on γ , and it is given for a dilute pair of spins (I_1, I_2) by

$$\mathcal{H}_D = -\left(\frac{\mu_0}{4\pi}\right) \frac{\gamma_1 \gamma_2 \hbar^2}{r_{12}^3} \left(\frac{3 \cos^2 \theta - 1}{2} \right) \times (3I_{1z}I_{2z} - \mathbf{I}_1 \mathbf{I}_2) \quad [1]$$

The coupling within a pair (or within a small group) of nuclei is well defined by their relative positions (distance r and angle θ), which makes their interaction inhomogeneous. The line shapes or dipolar splittings of dilute labels can thus be directly analysed to measure local

Table 1 Nuclear spin properties of ^1H and ^{19}F

Property	^1H	^{19}F
Natural abundance	99.98%	100%
Gyromagnetic ratio γ ($10^7 \text{ rad s}^{-1} \text{ T}^{-1}$)	26.7522	25.1815
Relative sensitivity (at constant field)	1.00	0.83
Resonance frequency at 11.74 T	500 MHz	470.4 MHz
Chemical shift range (total) (organic compounds)	– 20–30 ppm 0–12 ppm	– 400–800 ppm – 200–0 ppm
Shielding anisotropy (CSA)	30 ppm	200 ppm
Dominant relaxation mechanism	Dipolar	Dipolar, CSA

structural parameters or motional averaging. In an extended network of abundant spins, on the other hand, the dipolar interactions are more complex than in eqn [1] and they become highly nonlinear. This leads to homogeneous line-broadening by spin diffusion, which is much harder to suppress experimentally.

The main difference between ^1H and ^{19}F lies in the ranges of their isotropic and anisotropic chemical shifts (anisotropic = dependent on the orientation of the molecule in space, i.e. on its alignment with respect to the magnetic field direction). Unlike ^1H , the ^{19}F atom is rather polarizable, which makes the chemical shift very sensitive to local charge densities and hydrogen-bonding, and which also leads to significant solvent and temperature effects. **Table 2** provides a comprehensive list of isotropic ^{19}F chemical shifts for inorganic and organic solid compounds, as compiled by Miller. Referencing in the solid state usually relies on comparison with a separate sample of TMS for ^1H , or CFCl_3 for ^{19}F , rather than using internal or external chemical shift standards. An extensive list of chemical shielding anisotropies for ^1H and ^{19}F has been published by Duncan.

Methods for Studying Abundant and Dilute Spins

In the following overview of methods and applications in high-resolution solid-state ^1H and ^{19}F NMR it is instructive to consider different kinds of situations that the experiment may need to address. Depending on the abundance of spins, different line broadening mechanisms will be encountered, and different techniques are required to achieve high resolution. After a discussion of four such categories, some representative applications to various materials will be illustrated.

^1H NMR of Abundant Spins

In organic compounds, in polymers and in biological materials the ^1H -density is high and spin diffusion leads

to rapid dephasing of the magnetization. The resulting homogenous line broadening can only be fully suppressed by MAS when the spinning frequency ν_r is much higher than the static line width (which is typically around 50 kHz in rigid solids). Since modern commercial NMR probes can reach speeds of up to 35 kHz with small rotors, this is not usually sufficient to achieve complete homonuclear dipolar decoupling in rigid solids. Only samples with a high intrinsic mobility, such as liquid crystals and rubber-like materials, will give narrow lines under high-speed MAS, with well-resolved isotropic chemical shifts. Note that the chemical shielding anisotropy does not usually represent a problem for ^1H NMR, because it represents an inhomogeneous interaction. It is efficiently narrowed by MAS already at low spinning speeds, resulting in a narrow isotropic line plus a set of sidebands that are separated by multiples of ν_r .

As an alternative to averaging in real space, dipolar decoupling can also be achieved in spin space by using multiple-pulse sequences such as WAHUA-4, MREV-8 or BR-24. The efficiencies and spectral sweep-widths of these sequences are limited by the cycle time, e.g. to average a dipolar width of 50 kHz the cycle would have to be short compared to 20 μs . This places considerable technical demands on the probe design, namely short ring-down times ($\ll 10 \mu\text{s}$) and the capacity for short high-power pulses under high duty cycle. Homonuclear decoupling efficiency is further improved by Combined Rotation And Multiple-Pulse Spectroscopy (CRAMPS). Even though this kind of experiment was not considered in the past to be easily implemented, modern spectrometers can be more routinely adjusted with respect to accurate phase cycling and timing. CRAMPS measurements are usually carried out under quasi-static conditions (typically 2–3 kHz MAS), but recent experiments have also been designed for fast MAS (10–20 kHz) in combination with short windowless multiple-pulse sequences. To assign simple compounds, the line widths in a CRAMPS spectrum are often sufficient, even though they are still broader than in solution state ^1H NMR.

Figure 1 illustrates some sources of line-broadening that cannot be prevented even on a perfectly well-adjusted spectrometer. The resolution of the glassy polymer polystyrene is about an order of magnitude worse than that of crystalline adipic acid, which is partially attributed to the dispersion of chemical shifts in the amorphous material. Additionally, it has been recognized that the anisotropic molecular magnetic susceptibility provides a dipolar broadening mechanism for aromatic groups, which limits their peak resolution to about 0.3 ppm. Further difficulties in a CRAMPS experiment will be encountered when a group undergoes motions with a correlation time comparable to the pulse width, to the multiple-pulse cycle time, or to the sample spinning speed, as this can lead to severe losses in signal intensity.

^a Possibly an inconsistent assignment. Use with caution.

All shifts have been recalculated with respect to CFCl_3 as the reference.

Multidimensional spectroscopy plays an essential role in solution state ^1H NMR, by providing correlations through bonds (COSY, TOCSY), through space (NOESY), or to heteroatoms (HMQC, HSQC). Homonuclear 2D spectra of solids are only feasible when the sample possesses an intrinsically high mobility to give a sufficient resolution, which is the case for liquid crystals. Heteronuclear correlation (HETCOR) experiments, on the other hand, are a powerful tool to map even the very broad ^1H signals of a rigid molecule onto a second ^{13}C dimension via the dipolar coupling through space. Since ^{13}C possesses a chemical shift range of about 200 ppm, compared with 12 ppm for ^1H , the increase in resolution makes it possible to assign resonances in relatively large organic compounds and to study hydrogen-bonding in biological solids. During the evolution and mixing periods of a HETCOR experiment, the suppression of ^1H - ^1H homonuclear and ^1H - ^{13}C heteronuclear couplings can be achieved by multiple-pulse sequences and/or MAS. In the related wide-line separation experiment (WISE), where ^1H -line-widths are used as a measure of the respective segmental mobilities, the homonuclear interaction is allowed to be active during the evolution

period. Whereas HETCOR is applicable to sites carrying any number of protons, the dipolar chemical shift correlation experiment (DIPSHIFT) has been designed to determine the accurate bond distance in a particular heteronuclear spin-pair, e.g. of ^1H - ^{15}N in polypeptides.

Another sophisticated way of correlating spins with one another is possible by multiquantum spectroscopy, which can in principle resolve the connectivities of atoms that are present as an isolated cluster. Various multiple-pulse experiments have been designed to recouple isolated spins under fast MAS via multiquantum (or zero-quantum) coherences. When faced with an abundant network of ^1H , however, it is usually only feasible to monitor build-up rates qualitatively as a measure of the dipolar coupling strength. For example, when molecular motion reduces this interaction in polymers, the signal intensities after multiple quantum production can be interpreted in terms of the respective local dynamics.

A different kind of ^1H NMR application in polymers is the use of long-range spin diffusion to study the heterogeneity of the sample. In this experiment a gradient of magnetization is set up between different regions that can be differentiated either by their mobilities (i.e. amorphous

Figure 1 ^1H NMR CRAMPS spectra of amorphous polystyrene (top) and crystalline adipic acid (bottom), showing different degrees of resolution. Reproduced with permission of Elsevier Science from Gerstein BC (1998) ^1H NMR. In: Ando I and Asakura T (eds.) *Solid State NMR of Polymers*, vol. 84, pp. 166–189. Amsterdam: Elsevier Science.

and crystalline) or by their chemical shifts. During a subsequent storage period the magnetization will diffuse over distances of up to 30 nm per second, such that domain sizes can be estimated by choosing suitable delay times. In these systems a CRAMPS experiment may be applied to resolve groups of signals, and multiple-pulse sequences have even been used as a chemical shift filter to ‘catch’ a resonance and keep it aligned with the static magnetic field direction. Strictly, however, the experiments mentioned in this paragraph are derived from broadband experiments and do not contribute themselves to an improvement in resolution.

^{19}F NMR of Abundant Spins

The situation with abundant ^{19}F spins, e.g. in fluoropolymers and inorganic fluorides, is similar to what has been outlined for ^1H . The same basic experiments apply, although the much broader range of ^{19}F isotropic chemical shifts (see **Table 2**) affords an intrinsically better resolution. ^{19}F MAS spectra of rigid solids will be accompanied by a higher number of spinning sidebands due to the increased chemical shielding anisotropy (CSA). Technically it becomes more demanding to excite

uniformly the large spectral width of ^{19}F (90° pulse length of typically 1–2 μs), especially in multiple-pulse experiments which are quite sensitive to offset. To cover a broad spectral width in a CRAMPS experiment, it is essential to use the shortest possible cycle times. To that aim, the ring-down time of a probe can be reduced by Q -spoiling, which involves the addition of resistance to the RF circuit but has the disadvantage of requiring higher power levels for a given 90° pulse length. Alternatively, the signal can be built up in a pointwise fashion at the end of an incremented number of cycles. Since this single-point approach dispenses with the need for sampling during the pulse train, windowless or semi-windowless sequences can be used, although this method is associated with an obvious penalty in measurement time. In terms of hardware, a fast digitizer is required for ^{19}F NMR, and fluorine-containing materials should be avoided in the probe components. The relaxation mechanisms of ^{19}F are somewhat more complicated than those of ^1H , as they are affected not only by dipolar couplings but also by the chemical shielding anisotropy and hence magnetic field strength.

^{19}F NMR of Dilute Spins in the Presence of Protons

Dilute ^{19}F spins in a protonated environment do not suffer from direct homonuclear line broadening, but a new problem arises from the possibility of cross-relaxation to ^1H . In principle these heteronuclear interactions are inhomogeneous, and MAS should be effective for narrowing. However, the situation becomes complicated when strong ^1H – ^1H coupling leads to spin diffusion within the proton network, because this leads to a homogeneous dephasing of the ^{19}F magnetization. Therefore, to obtain well-resolved ^{19}F NMR spectra strong ^1H -decoupling is essential (ideally up to 250 kHz). A double-resonance $^{19}\text{F}\{^1\text{H}\}$ probe should thus be capable of handling high power levels on both channels, and efficient filters are required to separate the two frequencies which are only 6% apart. With increasing magnetic field strengths the filtering becomes easier. Probe design may nevertheless require new approaches, such as transmission lines or cavity resonators, especially when a third channel is to be included for a low-frequency nucleus. As a consequence of high-power ^1H -decoupling, the ^{19}F resonances will be affected by the Bloch–Siegert shift, which is given by the ratio

$$\Delta = (\gamma_{\text{F}} B_{1\text{H}})^2 / (\omega_{\text{F}}^2 - \omega_{\text{H}}^2) \quad [2]$$

where $\gamma_{\text{F}} B_{1\text{H}}$ is the magnitude of the ^1H -decoupling field at the ^{19}F resonance frequency. On a 4.7 T spectrometer (200 MHz for ^1H) the shift is typically a few ppm towards lower frequency, but it becomes less significant at higher magnetic field strength.

Figure 2 illustrates the effects of ^1H -decoupling, of MAS, and of intrinsic molecular mobility on the ^{19}F NMR spectrum of the fluorinated sterol diflucortolon-21-valerate (DFC). While the static ^{19}F line shape of the crystalline material shows no recognizable features (**Figure 2a**), ^1H -decoupling reveals the two underlying CSA tensors (**Figure 2b**). With additional MAS at moderate speed (**Figure 2c**), the isotropic chemical shifts are resolved (as marked by an asterisk), and the principal values of the tensors can be calculated from the spinning sideband intensities using the Herzfeld–Berger approach. To demonstrate the molecular mobility in a liquid crystalline environment, in the next example (**Figure 2d**) the hydrophobic DFC was incorporated at a total concentration of 10% (w/w) into lipid bilayers composed of dimyristoylphosphatidylcholine (DMPC). Two narrow lines appear in this ^{19}F $\{^1\text{H}\}$ MAS spectrum (**Figure 2d**), corresponding to the two ^{19}F -substituents on those sterol molecules that are partitioned into the bilayer. Since they undergo rapid long-axial rotation and restricted anisotropic tumbling, their total line width is less than the MAS spinning speed (5 kHz) and no sideband patterns are observed. Additionally, a residual contribution of crystalline material is visible in the same spectrum (**Figure 2d**), whose integrated intensity shows that DFC can only be dissolved up to 3.5% (w/w) in hydrated DMPC bilayers. Notably, the isotropic chemical shifts of DFC in the hydrophobic bilayer interior differ significantly from those in the crystalline environment, whereas they are rather similar (within 1 ppm) to the values obtained in CHCl_3 solution (**Figure 2e**).

An elegant way to distinguish ^{19}F -substituents based on their mobility or their proximity to protons is provided by cross-polarization (CP) from ^1H to ^{19}F , allowing, for example, the suppression of PTFE background signals. Having been originally developed under static conditions, this experiment can be used under MAS with some slight modifications. By choosing a short CP contact time, the ^{19}F -signals from immobile groups are selected since they are engaged in a rapid transfer of dipolar magnetization. Alternatively, the dipolar dephasing experiment can be used to select resonances of ^{19}F -spins that are in comparatively mobile domains or remote from protons. CP MAS can also be combined with inversion recovery measurements, since the ^{19}F relaxation tends to be affected by cross-relaxation to ^1H . The T_1 -values of ^{19}F are obtained either by direct polarization or by a suitable post-CP variable delay, whereas T_1 -relaxation of the protons is revealed by inserting a pre-CP delay on ^1H during the ^{19}F $\{^1\text{H}\}$ -experiment.

Homonuclear ^{19}F – ^{19}F correlations provide information about spin diffusion through space, as, for example, in a 2D spin-exchange experiment. This approach requires sufficiently fast MAS and ^1H -decoupling to achieve complete resolution, since any magnetization

Figure 2 ^{19}F NMR spectra of diflucortolon-21-valerate (DFC) under different experimental conditions and in different environments, illustrating the effects of ^1H -decoupling, MAS and intrinsic molecular mobility.

exchange due to spectral overlap of the ^{19}F resonances has to be avoided. On the other hand, it may be desirable to stimulate a controlled magnetization exchange by introducing a certain spectral overlap under moderate

MAS speeds. That is, when the spinning sidebands of one signal are allowed to overlap with the sideband pattern of a second signal, these two spins are recoupled by Rotational Resonance (RR). The RR experiment and related broadband recoupling schemes were originally developed to measure weak pairwise couplings between selective ^{13}C -labels and thus to determine their accurate distances (up to 7 Å). When applied to a fluorinated sterol, the RR effect was observed as a significant line-broadening rather than a dipolar fine-structure, which is consistent with rapid spin diffusion. Despite these difficulties, fluorinated substituents are desirable for RR and related experiments, because ^{19}F – ^{19}F distances could theoretically be extended up to 16 Å. In fact, long-range heteronuclear distances (^{19}F to ^{13}C or ^{31}P) have been successfully determined by Rotational Echo Double Resonance (REDOR) and Transferred Echo Double Resonance (TEDOR) experiments. Owing to the fast spin diffusion of the ^{19}F magnetization it was usually necessary to observe the REDOR effect on the low-frequency channel under ^{19}F -dephasing. Overall, many of the experiments known for ^{13}C can be adapted for dilute ^{19}F spins provided that efficient ^1H -decoupling is available, and there is much potential for further development.

High-Resolution ^1H and ^{19}F NMR of Oriented Samples

Instead of averaging away the anisotropic nuclear spin interactions by MAS or multiple-pulse sequences, it is possible to take advantage of the anisotropy of these interactions, provided that macroscopically oriented samples are available. This kind of static solid-state NMR approach is entirely different from the experiments discussed above. It can lead to highly resolved ^1H and ^{19}F spectra with narrow lines, whose position carries information about the alignment of individual molecular segments. Oriented samples are typically prepared by stretching polymers or suitable proteins into fibres, or by aligning polymer films, liquid crystals or biological membranes on planar supports. For the most basic experimental set-up, the symmetry axis of the uniaxially oriented sample is aligned parallel to the static magnetic field direction. That way all groups of any one kind in the molecule will experience the same nuclear spin interaction. This interaction is characterized by a single value of the relevant anisotropy tensor, for example by the CSA tensor or by the inhomogeneous dipolar coupling to another dilute spin (see eqn [1]). The resulting ^1H or ^{19}F NMR signal will thus consist of a narrow line, whose resonance position reveals the geometric relationship between the respective tensor and the macroscopic axis of the oriented sample. In contrast, an un-oriented static

sample gives rise to a broad powder line shape, and an MAS spectrum is simply reduced to the isotropic resonance. In practice, the effective line width of an oriented sample is limited by the quality of alignment, plus any residual broadening.

Applications of ^1H and ^{19}F NMR

Inorganic Solids

The classic inorganic compound investigated by solid state ^1H NMR is $\text{CaSO}_4 \cdot x\text{H}_2\text{O}$. As a powder it yields the well-known Pake pattern, and oriented single crystals have been used to analyse the angle-dependence of the homonuclear dipolar coupling. Today, most ^1H NMR applications employ fast MAS, preferentially at high field. Studies of hydroxyl groups in zeolites, in glasses, and on the surface of catalysts yield information about their local structure and acidity. Using ^{19}F MAS or CRAMPS experiments, the isotropic chemical shifts of many inorganic fluorides have been determined (see Table 2). Here, CaF_2 and its fluorohydroxyapatite derivatives $\text{Ca}_5(\text{PO}_4)_3\text{F}_x(\text{OH})_{1-x}$ are of particular interest due to their relevance in human dental enamel, in bone implants, as well as in fluorescent lights. In addition, the fluoride species formed upon adsorption onto alumina, silica, clays, zeolites or related materials have attracted attention in view of their role as catalysts or molecular sieves.

Organic Molecules

Solid-state ^1H NMR constitutes a powerful approach to investigate the hydrogen-bonding and ionization states of small organic compounds, with similar applications in structural biology. High-resolution ^1H MAS and CRAMPS experiments have provided isotropic chemical shifts and CSA tensors for many simple molecules. In several instances a direct correlation with hydrogen-bonding lengths could be demonstrated, e.g. for amino acid carboxyl groups. Well-resolved ^1H – ^{13}C HETCOR spectra have been obtained for various drugs (e.g. ibuprofen) and oligopeptides. With regard to ^{19}F NMR, apart from the isotropic chemical shift values the ^{19}F CSA tensors have been characterized for various aliphatic (e.g. silver trifluoroacetate, $\text{C}_8\text{F}_{17}\text{SO}_3\text{Na}$) and aromatic (e.g. pentafluoroaniline, perfluoronaphthalene) compounds by analysing the spinning sideband intensities. Pharmacaceutically active sterols with one, two, and three ^{19}F -substituents (cf. Figure 2c) were used to establish more advanced $^{19}\text{F}\{^1\text{H}\}$ and triple-resonance $^{13}\text{C}\{^{19}\text{F}\}\{^1\text{H}\}$ NMR experiments. Since the 1D spectra were found to be rather sensitive to sample polymorphism, they can be used to detect different crystalline forms that may exhibit different pharmacological activities.

Polymers and Rubbers

High-resolution ^1H NMR spectra of polymers are most readily obtained when the material possesses an intrinsically mobile backbone or side-chains (e.g. an elastomer), when measured at high temperature, or when a deuterated solvent has been imbibed (e.g. CDCl_3 in PMMA, or a swollen functionalized resin carrying a bound product). For more rigid polymers, sufficiently narrow line widths have been achieved with the aid of fast MAS or CRAMPS to resolve aliphatic and aromatic resonances. Proton line widths and relaxation times have thus been used to describe segmental mobilities and crystallinity, to assess phase separation in co-polymers (e.g. PS-PVME), or to examine hydrogen-bonding and acidity (e.g. in PVA or polysiloxanes). Unlike the case with protonated polymers, where $^{13}\text{C}\{^1\text{H}\}$ NMR tends to be the method of choice, fluorinated polymers give strongly broadened ^{13}C NMR spectra, which creates the need for direct ^{19}F -observation. Owing to the wide chemical shift range of ^{19}F NMR, simple broadline/relaxation NMR studies were quite popular in the past, but many high-resolution experiments have been demonstrated since. Studies of commercially important materials include PTFE, $(\text{CF}_2\text{CF}_2)_n$; PTrFE, $(\text{CF}_2\text{CFH})_n$; PCTFE, $(\text{CF}_2\text{CFCl})_n$; and PVDF, $(\text{CF}_2\text{H}_2)_n$; as well as co-polymers of the latter material with HFP, $(\text{CF}_2\text{CFCF}_3)_n$; TFE, $(\text{CF}_2\text{CF}_2)_n$; and CTFE, $(\text{CF}_2\text{CFCl})_n$. Some advanced triple-resonance REDOR experiments have been performed with ^{19}F -labels in dendrimers and in nanospheres, to visualize their packing density and the distribution of sequestered ligands, respectively.

Liquid Crystals and Lipid Bilayers

The fast long-axial rotation ($\tau_c \approx 10^{-10}\text{ s}$) of liquid crystalline molecules leads to a partial averaging of the anisotropic interactions, thus improving the basic spectral resolution. For example, fast MAS of hydrated phospholipid dispersions yields well-resolved ^1H -NOESY spectra with distinct NOE cross peaks. Another important property of liquid crystals lies in the local alignment of the molecules about a director axis, which makes it useful to prepare macroscopically oriented samples. In a mechanically oriented sample, quasi-isotropic ^1H NMR spectra should be accessible by aligning the static sample axis along the magic angle. That way the intrinsic rotational diffusion of the molecules will average all anisotropic interactions to zero, although in practice any mis-alignment and slow collective motions of the molecules will reintroduce some line broadening. As an example, **Figure 3** illustrates the ^1H NMR spectra of an un-oriented dispersion of DMPC (**Figure 3a**) versus an oriented sample on glass plates (**Figure 3b**) aligned at the magic angle. Resolution can now be further enhanced by slowly spinning the oriented sample around the magic

Figure 3 ^1H NMR spectra of DMPC bilayers as an un-oriented lipid dispersion (a), and as a macroscopically oriented sample that is aligned along the magic angle (b). The resolution is further improved by MAOSS at 200 Hz (see text). Reproduced with permission of Academic Press from Glaubitz C and Watts A (1998) *Journal of Magnetic Resonance* 130: 305–316.

angle, which is called Magic-Angle Oriented Sample Spinning (MAOSS). The spectrum in **Figure 3a** shows narrow lipid signals (^1H line widths of 10–30 Hz) at a spinning speed of only 200 Hz, which compares favourably with the resolution achieved for lipid dispersions under high-speed MAS (14 kHz) or at a much higher magnetic field strength (17.6 T). It appears hopeful that even the signals of membrane-bound polypeptides (e.g. gramicidin, M13 coat protein) may be resolved using either of these MAS approaches.

Selective ^{19}F labelling of lipids has contributed to a better understanding of the structural and motional properties of artificial model bilayers as well as biological membranes (e.g. of the bacterium *Acholeplasma laidlawii* when fed with ^{19}F -labelled fatty acids). On the basis of early broadline NMR investigations, resolution has been improved by using oriented samples and multiple-pulse experiments to select certain anisotropic spin interactions. For example, the local order parameter of a particular acyl-chain segment can be calculated from the

dipolar splitting of the corresponding CF_2 -labelled group. **Figure 4** illustrates how the ^{19}F – ^{19}F dipolar coupling of 4,4-DMPC- F_2 can be extracted, which is not resolved in the normal ^{19}F NMR spectrum of an un-oriented lipid dispersion (**Figure 4a**), unless additional ^1H -decoupling is applied (**Figure 4b**). Alternatively, and

without any need for ^1H -decoupling, the Carr–Purcell–Meiboom–Gill (CPMG) multiple-pulse sequence is able to suppress all unwanted line-broadening interactions such that only the desired homonuclear ^{19}F coupling remains in the shape of a Pake pattern (**Figure 4c**). By extending the CPMG experiment to an oriented sample that is aligned with its symmetry axis perpendicular to the magnetic field (**Figure 4d**), an even better resolution ($<50\text{ Hz}$ line width) is achieved.

Peptides and Proteins

Solid-state NMR lends itself to the structural analysis of proteins that do not crystallize, or when details about their functional mechanism or hydrogen-bonding pattern are to be investigated. For example, long-range distances have been measured by heteronuclear REDOR experiments on enzymes prepared with specifically ^{19}F -labelled side-chains in the frozen or lyophilized state. In this way it could be demonstrated that the substrate-binding cleft of 5-enolpyruvylshikimate-3-phosphate synthase closes upon ligand binding, whereas the binding pocket of tryptophan synthase remains largely unperturbed.

Another, different kind of NMR approach has been developed to investigate the structure of membrane-associated peptides and proteins. This method relies on the use of oriented membrane samples, and it measures the ^1H -heteronuclear dipolar coupling and ^{15}N -CSA to determine the orientation of a labelled ^1H – ^{15}N bond in the polypeptide backbone. To build a full molecular structure from such orientational constraints, usually a series of selectively labelled peptides have to be prepared and the alignment of each single backbone segment is then measured step-by-step. A large number (>100) of signals from a uniformly ^{15}N -labelled membrane protein were successfully resolved, using a 2D PISEMA experiment with homonuclear Lee–Goldburg decoupling. Once an assignment strategy for this novel approach is developed, solid-state NMR will provide a set of tools for a comprehensive structural analysis of membrane proteins.

Figure 4 ^{19}F NMR spectra of 4,4-DMPC- F_2 as an un-oriented lipid dispersion without ^1H -decoupling (a), and with ^1H -decoupling (b). The dipolar splitting Δ_{FF} is directly resolved without ^1H -decoupling in the CPMG experiment (c), and the lines are sharpened further when an oriented sample is prepared and aligned perpendicular to the magnetic field (d). Symbols

$A_k B_l$ and $A_r B_s$	are vapour species in the binary system A–B
E_{th}	threshold energy
I_{ij}	measured ion current of ion i originating from molecule j
$I_i = \sum_j I_{ij}$	measured current of ion i
$I_i = \sum_j I_{ij}$	total ion current from molecule j
M_i	mass of ion i
M_j	mass of vapour specimen j
$N_A(N_B)$	mole fraction of A(B)
P_i	partial pressure of ion i
P_j	partial pressure of molecule j
P_{ref}, P_j	pressure of reference and investigated samples
q	weight of sample
S_{eff}	orifice area
σ_j	total ionization cross-section of molecule j
σ_{ij}	partial ionization cross-section of molecule j
ν	stoichiometric coefficient of chemical reaction

As a new research field, high temperature mass spectrometry was established in the early 1950s. Of special value was the combined use of the classic Knudsen effusion method and mass spectral study of the evaporation products of inorganic compounds (the KCMS technique). The first review appeared as early as 1959 and contained data for approximately 120 systems and compounds which had been studied by that time.

Currently, high temperature mass spectrometry is one of the most powerful methods in high temperature chemistry. A particular feature of this method is a high temperature molecular beam source, namely a Knudsen (or effusion) cell. A Knudsen cell is an isothermal enclosure with a small orifice of precisely known dimensions. Vapour molecules escape through the orifice at a rate assumed to equal the equilibrium rate of collisions with the wall of the cell. Total vapour pressure inside the Knudsen cell has to be less than 10 Pa to ensure molecular flow conditions. The effusion cell with the substance under investigation is placed inside the mass spectrometer

near an ionization chamber. By increasing the temperature of the Knudsen cell, the equilibrium pressure of the sample also increases, and usually a measurable signal can be detected from a pressure of 10^{-7} Pa inside the cell. Thus, the working range of the sample pressures in high temperature mass spectrometry is 10 – 10^{-7} Pa. After passing collimating slits, the molecular beam goes through the ionization chamber where electron impact ionization takes place. As usual in mass spectrometry, the electron energy is approximately 40–60 eV and can be changed to measure appearance energies.

Measurements of the ion current intensities provides the partial pressures of individual species inside the Knudsen cell and equilibrium constants of gas phase and heterogeneous chemical reactions. Thermal ionization of samples inside the Knudsen cell also takes place at high temperatures. These thermal ions are in equilibrium with the neutral species and can be drawn out from the cell by a weak electrostatic field and their partial pressures measured. This provides the equilibrium constants of gas-phase ion molecule reactions. As a result, the following thermodynamic data can be obtained: molecular and ion composition of the vapour; enthalpies and Gibbs free energy of gas-phase and heterogeneous chemical reactions; enthalpies of formation, Gibbs free energies, electron affinities and ionization energies for vapour species (molecules, positive and negative ions); activities of the components in mixtures, partial and integral Gibbs free energies of mixing and Gibbs free energies of formation of solid compounds in the mixture.

Knudsen Cell–Mass Spectrometer Equipment

Mass Analysers

In principle, any type of mass analyser can be coupled with the Knudsen cell system. As a rule, a mass range up to 1000 a.m.u. and resolution near 800 are sufficient for refractory material investigations. A single focusing magnetic sector field is used in most cases for mass analysis of effusion beams. Quadrupole and time-of-flight mass spectrometers are also applied. More expensive double focusing instruments provide high resolution and help to avoid interfering background ion intensities arising from ionization of organic impurities.

Knudsen Cells, Heating and Temperature Measurement Systems

Knudsen cells are mostly heated by resistance heaters or by electron bombardment. In the first case, the limiting working temperature of the cell does not exceed 1900 K and can be measured by thermocouples. Platinum–platinum/rhodium is applied up to 1300 K and tungsten–rhenium for higher temperatures. When electron bombardment is used, the upper temperature is limited by melting and evaporation of the cell material. Optical pyrometers of various types are the instruments of choice for temperature measurements in the range 2200–3000 K. Various types of Knudsen cell are used depending on the particular aim of the investigation. Stainless steel, quartz, nickel, graphite, tungsten or molybdenum may be applied as the cell materials. Protecting layers on the inner walls of a cell are also used to avoid chemical interactions between the sample and the cell material.

Some of the cells are shown in **Figure 1**. Two-compartment Knudsen cells (**Figure 1d**) are used if the vapour species formed from two different compounds with very different vapour pressures have to be investigated. They can also be used to get unsaturated vapours. The second compartment is replaced by a gas inlet system if gases are involved in the chemical reactions to be studied. ‘Russian doll’ type and a twin cell with a connecting channel (**Figure 1b** and **1c**) allow generation of saturated and unsaturated vapours of the sample.

Multiple Knudsen cells (**Figure 1e** and **1f**) are used for the determination of chemical activities. One cell contains a reference compound, whereas the others contain mixtures having different compositions. A comparison of the

vapour pressures in the different cells gives the activities of the components and differences between the sublimation enthalpies of the samples.

Local heating of the sample to higher temperatures can be provided by a laser. Containerless heating and free evaporation take place under such conditions. Local heating is widely used in cluster formation studies.

Ion Sources

Conventional ion sources with electron impact ionization are utilized. Photo-ionization and different types of electron energy selectors are applied to improve the accuracy of ion appearance energy measurements. The electron beam is always perpendicular to the effusion beam. The ion beam can be coaxial with the effusion direction or perpendicular to both the electron and the effusion directions. Both types of KSMC instruments are shown in **Figures 2** and **3**.

Thermal ionization of samples inside the Knudsen cell takes place at high temperatures and the Knudsen cell can itself be a source of thermal ions. The charge and quantity of escaping ions depend on the draw-out potential in front of the effusion hole. A combined ion source can operate in two modes, to register either neutral or charged particles escaping from the cell.

At an ion pressure of less than 10^{-8} Pa, the Debye shielding radius becomes larger than the linear dimension of the cell and the concentrations of positive and negative ions in the cell are not equal. Changing the electron work function of the inner surface of the cell can increase the concentration of the ions of interest.

Deflection plates are placed behind the exit slit of the ion source. The vector of the electrostatic field is coaxial with the sector magnetic field vector. The plates permit measurement of the ion kinetic energy distribution in the direction coinciding with the vector of the magnetic analyser field strength.

Background and Legitimate Signal

A problem which is equally important for both neutral and thermal ion registration is separation of the legitimate signal from the background. In neutral species studies, the legitimate signal is separated from the background by use of a movable shutter impeding the passage of the molecular beam to the ionization cell. In thermal ion studies, the signal is separated and located by means of deflecting plates. Because the electrostatic draw-out field has an axial symmetry and the axis of symmetry passes through the centres of the effusion hole and of the draw-out lens, the ions generated away from the axis (in the space between the cell and the lens) have an additional velocity in the direction normal to the axis of symmetry. This

Figure 1 (a) Knudsen cell; (b) Russian doll; (c) twin cell with connecting channel; (d) two compartment cells; (e) twin cell; (f) four Knudsen cell units (multiple cells).

Figure 2 Knudsen cell-sector magnetic mass spectrometer with coaxial ion and molecular beams.

Figure 3 Knudsen cell-sector magnetic mass spectrometer with perpendicular ion and molecular beams.

additional velocity component can be readily fixed by using the deflection plates. The use of these plates allows one to discriminate between the ions drawn out from the effusion hole (the legitimate signal) and those appearing on the outer surface of the effusion cell, protective screens, etc. (the background). Moreover, the method makes it possible to monitor the surface and to locate the place of sample evaporation (Figures 4 and 5).

Owing to the high temperature in the surroundings of the Knudsen cell some additional units are installed. There is a water jacket around the heating assembly and a

target cooled by liquid nitrogen to condense the effusion beam escaping from the Knudsen cell.

A valve between the Knudsen cell compartment and the ion source is useful and makes possible a fast change of sample in the cell without changing the parameters of the ion source. The Knudsen cell and heating assembly are fixed on a moving plate and can be shifted relative to the ionization chamber entrance slit. This allows one to find the appropriate positions of the electron and effusion beams which give the highest ionization efficiency.

Ionization Efficiency Curves and Cross-Sections

Ionization efficiency curves are plotted in the electron energy range 5–50 eV and ion appearance energies are determined in most cases. The threshold law is written as $I = \text{const}(E - E_{\text{th}})^{n-1}$, where n is the number of electrons leaving the collision area. In the case of the formation of singly charged positive ions, the linear extrapolation of the linear part of the ionization efficiency curves is widely used to find the ion appearance energy. The ionization cross-sections of atoms can be measured for

different ionization energies between 0 and 220 V in steps of 1 eV and their maximal values are located in the range 40–60 eV. These data are used in Knudsen effusion mass spectrometry; the calculated maximum values are considered to be in agreement within 20% with the experimental data if the ionization cross-sections are compared at the same energy.

Ionization cross-sections of molecules can be obtained from those of atoms by applying the additivity rule postulated by Orvos and Stevenson in 1956. The ionization cross-section calculated in such a way is a total for the electron energy in the range 40–60 eV. Fragmentation always takes place at such electron energies, and the mass spectrum of a molecule gives the ratios of partial cross-sections with respect to the base peak. The total ionization cross-section is the sum of the partial ones. It is generally accepted that the above additivity rule gives a value which differs from the experimental one by not more than a factor of 2. This rough estimate is only correct for the total ionization cross-section. There are two limiting cases in Knudsen cell mass spectrometry: the first is when the molecular ion peak is the base peak and its partial ionization cross-section with respect to the total is more than 80%. In the second case, the molecular ion peak is small and its partial ionization cross-section is less than 10% of the total. Treatment of the experimental data and the experimental approaches are essentially different in these cases. In the first case, measurements of the molecular ion intensities are sufficient for the reliable interpretation of the experimental data. In the second case, one has to know the fragmentation pattern (mass spectrum) of each vapour species and calculate the total ion current intensities for each vapour species. This task is rather complicated because a particular feature of high temperature vapour is the existence of vapour species which cannot be isolated as individual compounds and whose mass spectra cannot be measured in the previous runs. The superposition of the same fragments formed from different species takes place and ion current intensities have to be apportioned between each species.

The total ionization cross-section is a function of the electronic states of a molecule. It does not significantly depend on temperature in the one- to two- hundreds degree temperature range. It is not a case of partial cross-sections which depend on vibrational states. The temperature dependence of the mass spectrum of the individual molecules is well known and has to be taken into account before the experimental data are interpreted.

Relationships between Ion Intensities and Partial Pressures of Vapour Species

The relation between the measured ion current intensities and partial pressures of the neutral species inside

the effusion cell can be written as follows:

$$p_j = \frac{k}{\sigma_{ij} I_{ij} T} \quad [1]$$

$$p_j = \frac{k_i}{\sigma_j \sum I_{ij} T} = \frac{k}{\sigma_j I_j T} \quad [2]$$

where p_j is the partial pressure of molecule j , k is the sensitivity constant, σ_j is the total ionization cross-section of molecule j , σ_{ij} is the partial ionization cross-section of molecule j , I_{ij} is the measured ion current of ion i originating from molecule j (I is calculated allowing for the isotopic composition of the elements and the secondary multiplier gain), $I_j = \sum_i I_{ij}$ is the total ion current from molecule j , T is the temperature of the effusion cell. While the thermal ions escaping the effusion cell are recorded the corresponding equation relating the measured ion currents and ion pressures inside the effusion cell is given as:

$$p_i = C I_i M_i^{1/2} T^{1/2} \quad [3]$$

where p_i is the partial pressure of ion i , C is the sensitivity constant and M_i is the mass of ion i .

Mass Spectra and Gaseous Species

The chemical formula of the ions in the mass spectrum is obtained from the mass of the ions and their isotopic distribution. The next step is the assignment of the observed ions to their neutral precursors in the equilibrium vapour and the calculation of the vapour species, partial pressures. Equations [1] to [3] reveal a set of tasks which have to be completed if calculated partial pressure values are to be reliable:

- determination of sensitivity, k and C in eqns [1]–[3] (calibration of an instrument);
- determination of molecular weights of vapour species, j ;
- apportioning the measured ion currents $I_i = \sum_j I_{ij}$, i.e. determination of values I_{ij} ;
- calculation of total σ_j or partial σ_{ij} ionization cross-sections.

The last three points relate to neutral species only.

Molecular Weight of Neutral Species

Molecular ions and ion fragments have to be identified. The main approach is based on efficiency curve measurements and appearance potential estimates. For example, consider bismuth oxide. The ionization energy (IE) of Bi is 7.3 eV, IE of Bi_2O_3 is 9.5 and IE of Bi_4O_6 is 9.0 eV. The expected IE of molecular ions with atomic composition shifted to bismuth have to be in the range 7.3–9.0. There are 6 ions in the mass spectrum of saturated bismuth oxide vapour of Bi_4O_5 , Bi_4O_4 , Bi_4O_2 , Bi_3O_4 ,

Bi_2O_2 and Bi_2O . The first three ions have IE 9.1, 10.0 and 10.3 eV and are treated as fragments, the next have IE 7.5, 7.9 and 7.5 eV and are considered to be molecular ions.

Apportion of Ion Currents

When molecular ions give the base peaks in mass spectra, one can decrease the electron energy and obtain a mass spectrum which mainly consists of molecular ions. The estimated total ionization cross-section can be utilized and the partial pressures of vapour species calculated. When molecular ions give only a minor peak in the mass spectrum, decreasing the electron energy does not give satisfactory results and therefore some thermodynamic approaches have been developed. These are based on the variation of ion current intensities with the isothermal change of vapour composition.

The isothermal change of vapour composition is governed by the thermodynamic laws, and their analytical expressions can be included in the equation that relates measured and apportioned ion currents. A variation of partial pressures at constant temperature can be achieved by changing the composition of the solid (liquid) phase equilibrated with the vapour. When an individual compound is under study, Knudsen cells of **Figure 1b**, **1c** and **1d** allow one to compare the saturated and unsaturated vapours at the same temperature and apportion the measured ion current.

Instrument Calibration

For thermal ions, the ratio of ion partial pressures is measured without calculation of absolute values. In the case of neutral species, the ratio and absolute values of partial pressures have to be determined in most cases. Two methods of calibration can be used: (1) The sensitivity k is determined by comparison with a reference compound having a known vapour pressure. The ratio of the ionization cross-sections of a sample and a reference compound must be calculated according to the additivity rule and theoretical values of atomic cross-sections. (2) The sensitivity k_j is determined directly by complete evaporation of a weighed amount of a sample, and if complete evaporation of two samples is carried out, the ratio of their ionization cross-sections can be determined. In the first case,

$$p_j = \frac{k}{\sigma_j} I_j T \quad [4]$$

$$p_{\text{ref}} = \frac{k}{\sigma_{\text{ref}}} I_{\text{ref}} T \quad [5]$$

and

$$p_j = p_{\text{ref}} \frac{\sigma_{\text{ref}}}{\sigma_j} \frac{I_j}{I_{\text{ref}}} \quad [6]$$

where p_{ref} and p_j are the pressures of the reference and investigated samples, respectively.

In the second case, the Herz–Knudsen equation is utilized:

$$q[\text{mol}] = s_{\text{eff}} (2\pi M_j R)^{-1/2} \int_0^t p_j T^{-1/2} dt \quad [7]$$

$$= B_j \int_0^t p_j T^{-1/2} dt$$

where s_{eff} is the orifice area, q is weight of sample; M_j is the mass of vapour specimen and R is the gas constant. Taking eqn [2] into account it can be written as follows:

$$q[\text{mol}] = B_j k_j \int_0^t I_j T^{-1/2} dt \quad [8]$$

Measurements of temperature, ion current intensities as a function of time, weight of sample and the orifice area make it possible to calculate k_j and P_j at any time during evaporation. If there are several species in the vapour, eqn [9] has to be written as

$$q = \sum_j B_j k_j \int_0^t I_j T^{-1/2} dt \quad [9]$$

Dynamic Range

The upper limit of vapour pressure in the cell is determined by the molecular flow through the effusion orifice. When the orifice diameter is 0.3–1.0 mm, the upper limit lies in the pressure range 1–10 Pa. A vapour pressure equal to 10^{-7} Pa is accepted as the lower limit for neutral species. In the case of thermal ions, the sensitivity of the instrument is 5–6 orders of magnitude higher, and the data fall in the range 10^{-6} – 10^{-12} Pa. On the other hand, the concentration of ions in the vapour is 6–7 orders of magnitude lower than that of the neutral species, and as a result the ion currents from neutral species and thermal ions are of the same order.

Second and Third Law Calculations

When partial pressures are measured, the equilibrium constants of the gas phase and heterogeneous reactions can be calculated and their temperature dependence plotted.

The equation $d/dT(\ln K_p) = \Delta H^\circ / RT^2$ allows the determination of reaction enthalpies from the slope of the curve $\ln K_p$ versus $1/T$ (second law calculation). As $K_p = \prod_i P_i^{\nu_i} = \text{const}$ $\prod_i f_i^{\nu_i} T^{\Delta \nu_i} = \text{const}$ $K_p(T)$ one can determine the enthalpy change from the slope of the curve $\ln K_p(T)$ versus $1/T$.

The equation $\Delta H^\circ = -RT \ln K_p + \Delta \phi^\circ T$ allows one to calculate reaction enthalpies from the absolute value of K_p (third law calculation), where $\phi^\circ_T = -(G^\circ_T - H^\circ_0)/T$.

Determination of Activities

According to the definition of activity, a_j is the ratio p_j/p_j^0 , and putting ion current intensities I_j instead of partial pressures one has $a_j = I_j/I_j^0$. Even in the case of a binary mixture, not less than 10 samples of different composition have to be tested to obtain reliable data for the activities of both components in the complete range of composition. Two approaches have been developed to increase the efficiency of this type of measurement.

One of them is the multiple Knudsen cell which allows one to obtain activities for several mixture compositions during a run. Another is the isothermal evaporation method (IEM) which gives activities as a continuous function of the melt composition. The isothermal evaporation process should be carried out rather slowly (1–3% per hour) and can be considered a sequence of equilibrium states under such conditions. Simultaneously, ion current intensities are recorded as a function of time. Experimental data taken in such a way give ion current intensities as a function of time, integrals $\int_0^t I_{ij} T^{1/2} dt$ and derivatives of two types $dI_j(t)/dt$ and $dI_j(t)/dI_{\text{ref}}(t)$. These data can be transposed into partial pressure and activity depending on the melt composition. The mathematical part of IEM which makes this transformation possible is based on the Herz–Knudsen and Gibbs–Duhem equations.

There are many binary systems whose vapour contains mixed associates and a large number of vapour species. The virtue of the KSMC method is the possibility of directly determining the partial pressures of vapour species, rather than the total pressure in the system. These advantages of mass spectrometry are widely used in thermodynamic research into two-component systems. If there are mixed species $A_k B_l$ and $A_r B_s$ in the saturated vapour of system A–B, the Gibbs–Duhem equation $\sum_j N_j d \ln a_j = 0$ can be written as

$$\frac{d \ln P(A_r B_s)}{d \ln P(A_k B_l)} = \frac{r N_B - s N_A}{k N_B - l N_A}$$

where $N_A(N_B)$ is the mole fraction of A(B) in the solution. Partial pressures can be replaced by ion currents and any pair of vapour species can be treated in accordance with the Gibbs–Duhem equation. In the simplest cases ($r=1$, $s=0$, $k=0$, $l=1$) it will be

$$\frac{d \ln p_A}{d \ln p_B} = -\frac{N_B}{N_A} = \frac{d \ln I_A}{d \ln I_B}$$

and for $r=1$, $s=-1$, $k=0$, $l=1$

$$N_A d \ln \frac{p_A}{p_B} + d \ln p_B = 0 = N_A d \ln \frac{I_A}{I_B} + d \ln I_B$$

Different forms of Gibbs–Duhem equation are used and the choice of independent variables is determined by

the vapour species being easily registered. The replacement of low intensities by the ratio of measured ones is a general approach in KCMS. Any type of equilibrium involving molecules j can be used for this purpose. For example, consider the reactions $A + B \rightleftharpoons AB$

$$K_p = \frac{p_{AB}}{p_A p_B}$$

and p_A may be replaced by the ratio p_{AB}/p_B .

Applications

Vapour Species and Their Thermodynamic Properties

All major classes of inorganic compounds have been studied by KSMC. The discovery of new gas phase molecules and ions is considered a main achievement of KCMS. Thermodynamic properties of the newly discovered vapour species were also obtained and most of them can be found in reference books. Metal vapours consist of atoms and small amounts of dimers. The main vapour species of carbon is a trimer and a series of C_n ($n=1-8$) molecules were found in the saturated vapour. The main components of P, As and Sb vapours are tetramers. In the vapour of S and Se, a series of polymers with $n=1-12$ were observed with the most abundant species being S_8 and Se_6 . Heteroatomic molecules are always present in the vapour of mixtures of elements. The saturated vapour of inorganic compounds that evaporate in the temperature range 700–3000 K generally contains species formed by the dissociation of the base compound and a number of associates. Many interesting and unexpected examples can be found in the extensive database on the species in inorganic vapours. The existence of the dimers and trimers of oxides V_2O_5 , WO_3 and MoO_3 has been reported. Salts of oxygen-containing acids can be evaporated without decomposition to give small amounts of dimers. Mixtures of halides of alkali metals and halides of polyvalent metals give associates in the vapour and the electrical properties of such associates have been investigated.

Heterogeneous Reactions and Gas Phase Reactions

Gas phase reactions of any type can be successfully studied. The magnitude of the equilibrium constant is important. *Isomolecular* reactions $A + B \rightleftharpoons C + D$ do not require an absolute instrument calibration which makes them the most convenient and frequently observed type of reaction. This also concerns ion–molecule and electron exchange reactions. A bond dissociation energy is calculated from the equilibrium constants of the reaction

$MX_n \rightleftharpoons MX_{n-1} + X$. The sublimation enthalpy and dissociation enthalpy are determined from the equilibrium constants of the heterogeneous reactions $A_{solid} \rightleftharpoons A_{gas}$ and $AB_{solid} \rightleftharpoons B_{solid} + A_{gas}$.

Ion/Molecule Equilibrium in the Saturated Vapour

A study of the complex halogenides and salts of oxygen-containing acids by KCMS modified for ion/molecule equilibrium study (KCMS-IME) showed a very high concentration of ions in the saturated vapour (only 5 orders of magnitude less than the vapour pressure). These salts of alkali metals have large anions and as a result the enthalpies of heterolytic dissociation of the complex salts are much lower than those of alkali metal fluorides. For example, for the system $KF-33 \text{ mol\% } UF_4$, $T=1000 \text{ K}$, $p(KUF_5)=0.35 \text{ Pa}$; $p(K^+)=p(UF_5)=10^{-6} \text{ Pa}$. At such ion pressures the Debye shielding radius R_d (0.2 mm) is significantly smaller than the linear dimension of the Knudsen cell (10 mm). An electronless plasma is formed and the main vapour species are:

Molecules KF , K_2F_2 , KUF_5 , UF_4

Positive ions K^+ , K_2F^+ , $K_2UF_5^+$

Negative ions KF_2^- , UF_5^- , UF_6^- , $U_2F_9^-$

Electron Affinity Determination

Addition of complex alkali metal salts to a high temperature system leads to negative ion formation in the vapour. KCMS-IME can be applied to electron affinities and the estimation of negative ion enthalpies of formation. The EA of fluorides and oxides of transition metals in their higher oxidation states were determined. Almost all of these compounds have EA in the range 3.5–7.0 eV. Application of this method to fullerene vapours has yielded the electron affinities for the series of higher fullerenes C_n ($n=70, 72, \dots, 106$).

Activities in Mixtures and the Gibbs Free Energy of Formation of Solid Compounds

The determination of activities of components allows calculation of the partial and integral Gibbs free energy for the mixing of liquid and solid solutions. If solid compounds A_nB_m are formed in the mixture A–B, the Gibbs free energy of formation of these compounds from A and B may be calculated.

P–T–X Diagram Study

Measurements of the dependence of partial pressures on temperature along the liquidus (two-phase equilibrium between liquid and solid phases) and solidus (solid–solid) lines and partial pressure dependences on system composition at constant temperature give the total pressure

and vapour brutto composition as function of temperature and system composition. After these data are obtained, a T-X diagram can be transposed to a P-T-X diagram. Such diagrams are used in applied science, for example the growth of crystals and films by the vapour deposition method.

Homogeneous Range, Partial Pressures of Oxygen

KCMS is often used for the study of the homogeneous range of solid compounds. The partial pressure change can be easily selected. Isothermal evaporation is sometimes used to identify solid phase composition changes. Diffusion in the solid phase and enrichment of a surface layer by a hard volatile component demands special attention. When oxides, glasses or ceramics are studied, the oxygen partial pressure is of particular interest. One advance in the last decade is that very low partial pressures of oxygen can be calculated and controlled by measurement of the ratio of two negative ions (KCMS-IME). Oxides of variable valency metals are the source of these two ions and the equilibrium constant of the reactions $\text{MeO}_n^- + \frac{1}{2}\text{O}_2 \rightleftharpoons \text{MeO}_{(n+1)}^-$ has to be previously obtained. The same approach is used for activity determinations and is based on similar reactions $\text{A} + \text{B}^- \rightleftharpoons \text{AB}^-$ and the measurements of negative ion ratios $I(\text{AB}^-)$ to $I(\text{B}^-)$.

MRS	magnetic resonance spectroscopy

Introduction

In biological and medical sciences, traditionally NMR (nuclear magnetic resonance) spectroscopy has been either performed on tissue extracts or used in *in vivo* spectroscopy exploiting the noninvasive nature of the NMR experiment. Although both aqueous and lipophilic metabolites can be extracted from tissues, there is the question as to how representative a tissue extract may be of the original composition of the tissue – indeed many extraction procedures have distinct biases in terms of the classes of compounds that can be extracted. There is also a question as to whether all metabolites can be extracted or whether the extraction procedure modifies the metabolites directly (e.g., the oxidation of glutathione by perchloric acid). For example, aqueous metabolites surrounded by a lipid bilayer, such as neurotransmitter vesicles, may be poorly soluble in aqueous extraction media. To counter these problems one can perform *in vivo* magnetic resonance spectroscopy (MRS), the sister technique to magnetic resonance imaging (MRI), but this approach suffers from poor magnetic field homogeneity and overall sensitivity, limiting the total number of metabolites that can routinely be examined in many tissues. Although MRS has found extensive applications in following cerebral disorders, the biochemical changes recorded have been confined to the small number of metabolites that are readily observable using this technique.

NMR spectroscopy *in vivo* is impaired by a number of physical processes that result in broadening of spectral resonances. In addition, T_1 and T_2 relaxation times are often short, and in the case of fast T_2 , relaxation rates give rise to broader resonances. Furthermore, in heterogeneous samples such as tissue biopsies, anisotropic NMR parameters are not averaged completely to zero, also causing line broadening. A number of second-rank tensor interactions that might include dipolar couplings, chemical shift anisotropy, and bulk magnetic susceptibility differences – both across the whole sample and microscopically – all give rise to broadened lines in spectra.

Theory

For solid-state ¹H NMR spectroscopy of a biological tissue, chemical shift anisotropies are small, quadrupolar couplings are not present, and the J-coupling anisotropy is negligible. However, dipolar coupling and diamagnetic susceptibility anisotropy are both significant. Hence as an example, the dipolar Hamiltonian (in Hz) for two-spin one-half nuclei in a rigid solid is:

$$H_D/b = \sum (b/8\pi^2) \gamma_i \gamma_j r_{ij}^{-3} (3 \cos^2 \theta_{ij} - 1) (I_i I_j - 3 I_{zi} I_{zj}) \quad [1]$$

The value of the dipolar coupling depends on the angle (θ) that the internuclear vector makes with the field direction and the internuclear distance. For two protons close in space in a rigid solid, this can be of the order of 20 kHz, resulting in significant line broadening. The isotropic average of this is zero and is the reason why dipolar couplings do not appear in spectra measured on free solutions where molecular tumbling is possible. If there is some molecular motion, the angular term is partially averaged, and for tissues, where the viscosity of the cytoplasm and extracellular fluid is low, this can be considerable, leaving linewidths of the order of 1 kHz.

Furthermore, if the sample is spun at an angle α , an additional term of the form $(3 \cos^2 \alpha - 1)$ is introduced, and when $\alpha = 54.7^\circ$, that is, when $\cos \alpha = \sqrt{1/3}$, the so-called magic angle, then this angular term becomes zero and the line broadening associated with dipolar coupling term disappears. Thus, if samples are spun at a speed that is large compared to the partially averaged dipolar couplings at the magic angle, narrow lines can be produced that approach the linewidth detected in solution-state ¹H NMR spectra.

However, MAS NMR spectroscopy does not detect all the metabolites found within a tissue. Fats within restricted environments such as the cell membrane are subjected to dipolar couplings greater than those removed by the typically modest spin speeds used in tissue-based ¹H NMR spectroscopy, and thus, the lipids that are observed using ¹H MAS NMR spectroscopy are relatively mobile (rotationally, if not translationally). As an example of the effectiveness of MAS for tissue NMR spectra, **Figure 1** shows a typical result for a liver sample.

Sample Preparation

There is relatively little sample preparation required for most biological tissues that have been examined by

Figure 1 A comparison of ¹H NMR spectra from an intact piece of liver tissue either (a) static or (b) spun at 6000 Hz to demonstrate the spectral improvements produced by magic angle spinning, from Bollard ME, Garrod S, Holmes E, et al. (2000) High resolution ¹H and ¹H-¹³C magic angle spinning NMR spectroscopy of rat liver. *Magnetic Resonance in Medicine* 44: 201–207.

high-resolution MAS NMR spectroscopy. Sample sizes are typically 10–100 mg of tissue, depending on the rotor size and design used by a given MAS probe. These rotors are typically made of ZrO₂, which, of course, does not interfere with the observation of biologically relevant nuclei (e.g., ¹H, ¹³C, and ³¹P), and are relatively tough and durable, with a low thermal expansion that is important for a technique where it might be desirable to run samples across a range of 0–37 °C depending on the desired experiment. To ensure a reasonably homogeneous sample within the sensitive region of the MAS probe, Teflon inserts are typically used.

For NMR probes with a deuterium channel, samples are typically washed in D₂O, which also serves the purpose of removing any blood that might be found on the surface of the tissue and which could potentially confound shimming because of the paramagnetism associated with oxidized hemoglobin. The liquid also has the advantage that it precludes air from the insert of the MAS rotor, again improving the ease of shimming by reducing susceptibility effects across the rotor.

To ensure spinning side bands associated with the spectra are outside a 10–15 ppm region used to observe

metabolites in the tissue during ¹H NMR spectroscopy, samples are spun at a rotation rate that is in part dependent on the field strength of the magnet used. For a 600 MHz magnet, the rotation rate has to be at least 6000 Hz. With increasing spin rate the samples may suffer degradation, especially for softer tissues or cells, as centripetal force increases with the square of spin speed. This has led to a number of research groups developing pulse sequences, such as TOSS and PASS, for use with ¹H MAS NMR spectroscopy to minimize tissue degradation. However, even at speeds in excess of 6000 Hz, tissue degradation is minimal for all but the softest of tissues. Indeed, using Trypan blue staining it has been demonstrated that cultured neuronal and glial cells withstand the forces associated with spinning samples during MAS NMR spectroscopy. Furthermore, to minimize enzymatic degradation, samples can be chilled to within a few degrees of freezing during the acquisition of spectra. The design of MAS probes allows the chilling of the air used to spin the MAS rotors, although for work close to 0 °C, it may be more reliable to use nitrogen or dried air to prevent the formation of ice crystals within the probe.

Pulse Sequence Strategies for Observing Metabolites

One problem with observing metabolites *in situ* within tissues is that fats typically produce broad resonances across a wide area of the spectral region. Fatty acids consist of ¹H resonances from chemically very similar moieties and as a result naturally produce broad resonances even in solution. This effect is magnified in lipid droplets where movement may be restricted and in tissues where there is significant triglyceride content, such as adipose tissue.

For metabolites that are co-resonant with intense lipid signals, there are a number of different options available to detect the small molecules. The resonances associated with fatty acids typically have short longitudinal (T_2) relaxation times, and thus if spectra are acquired following a spin-echo-type pulse sequence, it is possible to 'edit-out' resonances from fats and observe metabolites that have more mobility. In this manner the Carr-Purcell-Meiboom-Gill (CPMG) pulse sequence has become popular to observe low molecular weight metabolites in intact tissues by MAS NMR spectroscopy. In this pulse sequence, magnetization is trapped in the transverse plane by a train of 180° pulses, whereas the signal from the broad, short T_2 resonances decays at a relatively faster rate than those from more mobile metabolites (Figure 2).

Alternatively, one can use the spin coupling along the molecular backbone in two-dimensional pulse sequences such as during COSY and TOCSY pulse sequences to separate co-resonant species. Although two-dimensional sequences may increase the acquisition time of the experiment, this is ameliorated by improved pulse sequences, probe design, and higher field strengths. Indeed, for pulse sequences like those based on J-resolved spectroscopy, the time requirement may not be significantly longer than conventional one-dimensional pulse sequences.

Probing the Cellular Environment with ¹H MAS NMR Spectroscopy

Using the cellular environment as a contrast mechanism, small and large molecules can be readily separated. It has already been discussed how the CPMG pulse sequence can be used to suppress the NMR peaks of larger metabolites like lipids. In a similar manner it can be used to 'select' for resonances associated with freely tumbling metabolites, rather than those bound to macromolecules or found in restricted environments that have shorter T_2 relaxation rates. The cellular environment may also affect longitudinal (T_1) relaxation rates, especially for water, where one may expect shorter T_1 relaxation rates in organelles like mitochondria, which have a significant

content of paramagnetic species. This also provides an alternative means to investigate rotational motion within the cell.

Alternatively, a pulse sequence can be used to edit spectra based on the differences in molecular diffusion coefficients. This involves the application of magnetic field gradients, which code the spatial position of the molecules. At some later time point, a decoding gradient is applied. If no molecular translation motion has occurred, the full NMR signal intensity is retained. However, if there is diffusion, signal intensity will be reduced in such a way that resonances can be effectively removed for fast-diffusing molecules. For field gradients rectangular in time, the attenuation of resonance intensity is given by:

$$A_g = A_0 \exp[-g^2 \delta^2 \gamma^2 D(\Delta - \delta/3 - \tau/2)] \quad [2]$$

where A is the signal intensity at gradient strength g , δ the time the gradient is applied for, γ the gyromagnetic ratio of the nucleus, τ a further short delay period, and Δ is the total diffusion time. Thus, data sets can be produced that are dependent on the cellular environment of the metabolites. In addition, a combination of T_1 , T_2 , and diffusion-weighted spectroscopy can be performed to probe the environment of a range of metabolites in intact tissues.

Biological Applications of MAS NMR Spectroscopy

The use of MAS NMR spectroscopy to follow metabolic changes in excised tumors was the first application of ¹H MAS NMR spectroscopy and is still the largest area of application. The first publications concerning high-resolution ¹H NMR spectroscopy date to 1996 and focused on the use of metabolic profiling of malignant lymph nodes, kidney carcinoma, and liposarcoma. The approach required only a small-size tissue, which made it an ideal adjunct to histology and in each case provided extra information to be able grade tumors in terms of either type or their malignancy. Since these pioneering studies, the use of MAS NMR spectroscopy has spread to include glioma, breast cancer, and prostate cancer.

One of the major advantages of ¹H MAS NMR spectroscopy for tumor biology is the capability of measuring both aqueous and lipophilic metabolites, as levels of both components are affected by tumor aggressiveness, malignancy, and cell death. Programmed cell death has been shown to selectively alter polyunsaturated fats in glioma, and this can be followed by ¹H MAS NMR spectroscopy. In addition, these lipid changes are accompanied by alterations in choline and nucleotide metabolism. An approach that relied on tissue extracts would separate out these processes across two different

Figure 2 Comparison of two ¹H MAS NMR spectra acquired from breast tumor using (a) the 1-D NOESY pulse sequence with presaturation applied during the relaxation delay (1.5 s) and mixing time (50 ms), with t_1 of 4 μ s, and (b) the CPMG pulse sequence with the relaxation delay of 1.5 s and the spin-echo delay of 2 ms with 100 loops (spin echoes) used to give a total spin-echo time of 400 ms. This pulse sequence attenuates resonances from broad components and in particular those associated with lipids.

fractions, and thus, the natural correlations between these processes would be lost. Similarly, malignancy of a range of tumors has been linked with choline-containing metabolites that are readily distinguishable by MAS NMR spectroscopy, but cannot be distinguished by *in vivo* MRS due to the reduced spectral resolution.

The technique has also proved sensitive not only to changes in tumor metabolism but also to drug toxicity, and is particularly useful at confirming organ-specific toxicity following the identification of biomarkers in biofluids as part of metabonomic studies. This approach has been used to correlate histopathology and urinary biomarkers by investigating 2-bromoethanamine toxicity in intact kidney

tissue. The drug induces mitochondrial dysfunction and inhibits fatty acyl-CoA dehydrogenases, with ¹H MAS NMR spectroscopy detecting a transient rise in glutaric acid, organic osmolytes, and fatty acid metabolism in the kidney. In a similar manner, MAS NMR spectroscopy has also been used to investigate α -naphthylisothiocyanate toxicity in the liver of rats, correlating changes in intact liver with global changes in systemic metabolism as measured in urine and blood plasma.

The small sample size of tissue required for ¹H MAS NMR spectroscopy is also a highly attractive feature of the technique. With high-quality spectra still being obtainable from as little as ~ 5 mg of tissue, it is possible to

sample organs in a region-specific manner. This has allowed the monitoring the effects of cerebral toxins such as kainic acid and 3-nitropropionic acid across different regions of the rat brain, with toxicity and histology being directly related by the co-preparation of ¹H MAS NMR spectroscopy and histology samples.

One of the first applications of ¹H MAS NMR spectroscopy was the investigation of cultured adipocytes and how such cell culture systems could be used to follow cell proliferation in adipocarcinomas. However, cells obtained from cultures have no connective structures to protect them from the mechanical degradation induced by spinning, and there was a possibility that improved spectral resolution arose from cell lysis rather than the physical averaging of dipole-dipole interactions and chemical shift anisotropy. However, trypan blue staining has shown that even following spin speeds in excess of 3000 Hz, there is only a modest increase in cells with compromised membranes, despite the large size of adipocyte cells. Similarly, this has been demonstrated in neuronal cells at spin speeds up to 6000 Hz.

This approach has also been used to follow drug toxicity in cell culture systems. Ishikawa cells are a human cell line derived from endometrial adenocarcinoma and, being hormone responsive, are useful for investigating drugs that modulate the estrogen receptor and hence that might be agents that will cause non-genotoxic carcinogenicity. ¹H MAS NMR spectroscopy of intact cells produced spectra with linewidths typically less than 5 Hz. Low molecular weight metabolites could further be investigated by applying a spin-echo sequence to edit out the more intense lipid signals (Figure 2). This approach allowed the definition of metabolites that vary in a dose response manner and could potentially be used as surrogate markers for the action of tamoxifen. In a similar manner, D-galactosamine toxicity has been followed in spheroids prepared from liver tissue, a type of hepatocyte preparation that still maintains cell-cell interactions.

One potential application of ¹H MAS NMR spectroscopy is applying the technique to provide a metabolic phenotype to correlate with other functional genomic tools, such as transcriptomics or proteomics. By allowing the dual observation of aqueous and lipid soluble metabolites, transcriptional changes can be correlated directly with all the metabolites present within a tissue rather than limiting the analysis to a particular subset. This approach has been used to examine orotic acid-induced fatty liver disease in rats, using a combination of metabolomics/metabonomics and transcriptomics. The metabolic changes detected in liver tissue consisted of increases in both lipid triglycerides and cholesterol esters, as well as choline-containing metabolites and their degradation products (Figure 3). Only by observing metabolites directly in the tissue could this range of compounds be followed.

Figure 3 ¹H MAS NMR spectroscopy of liver tissue from rats exposed to orotic acid over a 3-day time period. Orotic acid reversibly induces the accumulation of triglycerides in the liver of rodents. Clear increases in $-\text{CH}_2\text{CH}_2-$ and $-\text{CH}_3$ lipid moieties could be detected across the time period. These changes were also accompanied by alteration in the relative proportions of choline-containing metabolites and a decrease in both glucose and glycogen content within the tissues.

Other Nuclei

Although the proton is the commonest nuclei observed in high-resolution MAS NMR spectroscopy of biological tissues, many probes are designed to observe other nuclei. In particular, direct observation of ¹³C and ³¹P nuclei has been used to both confirm identification of metabolites as well as carry out more specialized types of analyses. The observation of ¹³C nuclei by MAS NMR spectroscopy allows the use of labeled substrates to probe metabolism in either intact tissues or cultured cells perfused with these substrates. This approach has been used to probe metabolism in perfused brain tissue slices and perfused heart tissue, examining both aqueous and lipophilic metabolites simultaneously and also lipid synthesis and the tricarboxylic acid cycle turnover simultaneously. Similarly, the use of ³¹P MAS NMR spectroscopy has allowed the observation of both high-energy phosphates such as adenosine triphosphate and phosphocreatine found in the cytosol and phospholipids used in membrane synthesis. This approach has proven to be particularly important in following metabolic changes in tumors and cancer cell lines.

Future Applications in MAS NMR Spectroscopy

Although spinning speeds used at present do not appear to produce significant damage in tissue samples, as

superconducting magnets move to increased field strength and spectrometers attain higher observation frequencies, samples will potentially be spun at higher speeds to remove spinning side bands from the region of interest. At some point, tissue degradation and the heating effect caused by spinning the sample will become significant. Thus, there is a need to develop pulse sequences that can operate at slower speeds but still provide high-resolution ¹H MAS NMR spectra. Indeed, the development of such approaches has allowed the development of a particular novel area of *in vivo* spectroscopy. As the spinning speeds decrease to a level of 1–4 Hz and using specialized pulse sequences, it becomes possible to spin whole organisms. Indeed, such an approach has been used to observe metabolites in the liver of a live mouse, and although not as resolved as obtainable from higher spinning rates, the spectra are a large improvement on regular *in vivo* spectra.

Even before these advances, the scope of being able to detect metabolites in tissues on a comparable scale to those used by histologists makes ¹H MAS NMR spectroscopy a desirable technique for many biologic studies. The combined use of laser capture and MAS NMR spectroscopy will allow the detailed study of complex, heterogeneous tissues such as those found in the brain. If the techniques required in MAS NMR spectroscopy can be fully automated, a routine step in histopathology will be sending sections to be analyzed by both histology and ¹H MAS NMR spectroscopy, providing another tier in the systems biology approach to understanding disease.

Introduction

The electronic absorption spectrum of an isolated molecule usually presents a series of sharp peaks whenever the laser excitation frequency ν_L equals the energy difference between the vibrational states, respectively, ν_0 of the electronic ground state S_0 and ν_1 of the electronically excited state S_1 , divided by the Planck's constant, $\nu_L = (E(S_1, \nu_1) - E(S_0, \nu_0))/h$. Those sharp peaks observed as vibrational progressions arise from rather long-lived excited states (typically in the nanoseconds range) and can possibly be superimposed on a broad continuum corresponding to very short-lived excited states (in the picoseconds or femtoseconds range). However, even under very dilute conditions, the electronic absorption spectrum of an assembly of identical isolated non-interacting molecules contains the contributions of several species corresponding to different chemical structures (tautomers) or different conformations. The situation is even more complicated in the case of molecules in a condensed phase. Even if each molecule contributes to the electronic spectrum through a narrow peak corresponding to its homogeneous lineshape, it interacts with its environment and thus acquires an absorption frequency depending upon the relative positions of its surrounding neighbors. The recorded absorption electronic spectrum then becomes the sum of an extremely large number of sharp peaks whose frequencies are independent and distributed randomly. The observed spectrum is broad and, in agreement with the central limit theorem, the corresponding inhomogeneous lineshape is a Gaussian distribution.

Hole-burning spectroscopy is a powerful method that allows the separation between different contributions of subsets of chromophores in the electronic spectrum of a molecular assembly. A pump ultraviolet (UV) laser is

tuned on an absorption frequency common to a given subensemble of molecular systems. This 'hole-burning' laser reduces the population of each concerned ground state S_0 that has been transferred to the excited state S_1 and thus 'digs' a narrow hole in the distribution of absorption frequencies (**Figure 1**). A probe laser is then scanned over the whole spectrum and interrogates the entire molecular ensemble. Owing to the hole-burning process, a dip appears in the absorption, transmission, or excitation spectrum any time the probe laser frequency is within the homogeneous lineshape of the 'burned' subset.

Spectral hole burning is thus a sequential two-photon process: first, a pump photon is used to burn a center, and then, a probe photon is used in the readout of the spectral hole.

Conformation-Specific UV–UV Hole-Burning Spectroscopy of Molecular Systems Isolated in the Gas Phase

The extremely low densities encountered in supersonic expansions or in ion traps do not allow the direct observation of the absorption of visible or UV photons. This difficulty is circumvented by monitoring the population of the excited state S_1 either by observing the fluorescence issued from this state (laser-induced fluorescence (LIF)) or using photons to produce ions (resonance-enhanced multiphoton ionization (REMPI)) (**Figure 1**). In the latter case, according to the energy separation between the S_1 level and the ionization limit, the same laser as the one inducing the $S_0 \leftarrow S_1$ electronic transition can be used (one-color REMPI) or a second ionizing laser would be necessary (two-color REMPI). The produced ions are mass analyzed, usually in a time-of-flight setup with the pulsed ionizing laser providing the ion starting time. This allows a direct *in situ* mass identification of the studied species.

Although molecular systems do not interact with their environment in the gas phase, they nevertheless can exist under different tautomeric forms or different conformations, each of them possessing a characteristic electronic absorption frequency. LIF or REMPI electronic spectra are thus congested due to the presence of several overlapping vibrational progressions belonging to several different absorbing species. Hole-burning experiments allow separate interrogation of each ensemble of tautomers or conformers present (**Figure 2**). A pump laser is

Figure 1 Left (top): IR-UV hole-burning scheme. A UV laser (light blue) is tuned on the $S_0 \leftarrow S_1$ electronic transition of a given conformer. Ions produced by a second UV laser (dark blue) are mass selected. A tunable IR hole-burning laser (red) is scanned. The resonant depletion of the ground state of the studied conformer induced by the IR laser is detected as a decrease in the ion signal. Left (bottom): REMPI spectrum of the FDAVS peptide, the structure of which is shown in the figure. The green arrows indicate the energies at which IR-UV hole-burning spectra are recorded. Right (top): IR-UV hole-burning spectrum of the FDAVS peptide. Right (bottom): Calculated IR absorption lines of 13 optimized conformers. tuned on the $S_0 \leftarrow S_1$ transition frequency of a set of molecules and selectively removes them from their ground state (selective depletion). In a LIF scheme, dips corresponding to the selected species appear in the dispersed fluorescence spectra. The hole-burning spectra establish which transitions in the LIF spectrum can be assigned to which conformer, thereby providing the UV spectrum of each conformation free from interference from the others.

In a REMPI scheme, a probe laser ionizes the selected molecules that have been selectively brought to their S_1 state. The evidence of the presence of different species and the discrimination of the spectral contribution of a particular tautomer or conformer in the electronic

spectrum is achieved through recording of mass-resolved hole-burning spectra obtained using ground-state depletion. This consists in recording the variation of the mass-selected species ion intensity produced by the probe laser whose wavelength is fixed on a particular spectral feature as a function of the wavelength of a pump laser triggered a few hundreds of nanoseconds before the probe laser. When the pump laser is resonant with one of the absorption bands of the probed tautomer or conformer, it depopulates its ground state, resulting in a strong decrease in the signal generated by the probe laser. Since the probed signal is recorded as a function of the pump laser wavelength, the resulting spectrum is composed of downward peaks starting from a given signal level.

Conformation-Specific IR-UV Hole-Burning Spectroscopy of Gas-Phase Molecules and Complexes

The double resonance hole-burning procedure can be extended in the infrared (IR) region. UV radiation from a probe laser is tuned to a chosen spectral feature of interest of molecules. A given tautomer or conformer is then selected. An intense IR ‘burn’ laser is scanned over the IR ‘fingerprint’ range and promotes selective ‘hole burning’ by transferring population out of the probed ground-state level. The dips observed in the LIF or REMPI signals reveal the vibronic features of the UV-selected species. Overlapping REMPI spectra, associated with different tautomers or conformers or cluster structures, are then disentangled and identified by IR-UV laser ‘hole-burning’ experiments. When the pump IR is scanned, one obtains the IR absorption spectrum of the UV-selected species. A great advantage of the IR-UV scheme over the UV-UV scheme is the following: Calculations of excited states of molecular systems are considerably more difficult and less reliable than those of ground states. Reliable predictions of the IR absorption spectra of the different tautomers or conformers of

molecular species containing up to 100 atoms can be obtained from density functional theory (DFT) calculations using reasonable basis sets (such as the Gaussian 6-31 + G*). With the use of scaling factors specific for each vibrational mode, harmonic calculations can reach a typical prediction accuracy of 10 cm^{-1} . The comparison between predicted and observed IR spectra then provides an unambiguous assignment of mass- and structure-selected species. This method has been applied, for example, for the determination of nucleobase pairs, pentapeptides, or disaccharides structures.

Hole-burning spectroscopy can also be applied to probe the vibrations of weakly bound molecular complexes. The frequency of a UV probe laser is fixed on a complex-specific REMPI fingerprint band, whereas an IR laser is resonantly tuned on an intramolecular bond frequency such as an O–H, C–H, or N–H stretch. IR vibrational redistribution (IVR) then takes place and if the IR photon energy exceeds an intermolecular binding energy, the excited complexes predissociate. The corresponding hole in the ground-state population is monitored by the UV laser and appears as a dip in the ion yield of the IR excited species. This method combines the high selectivity and sensitivity of detection of REMPI

mass spectrometry and the structural information brought by vibrational spectroscopy.

Hole-Burning Spectroscopy of Molecular Systems in Condensed Phase

Optical hole burning is a powerful tool for spectroscopy of chromophore molecules embedded in solvents, crystalline and amorphous materials, or proteins, making it possible to overcome the resolution limit imposed by inhomogeneous broadening brought by the different environmental conditions, structural disorder, strains, and imperfections. In addition to the vibrational and electronic degrees of freedom of a studied molecule, the vibrations of the surrounding solid, called phonons, must be taken into account. The intrinsic or homogeneous spectral linewidth Γ_{hom} of a single embedded molecule is related to an effective optical dephasing time T_2 given by $(1/T_2) = (1/2T_1) + (1/T_2^*)$. T_1 is the population decay time or excited-state lifetime (equivalent of the longitudinal relaxation time in NMR) and T_2^* is the pure dephasing time. Spontaneous radiative and radiation-less decay processes of the excited state do not contribute to T_2^* , which is due to electron-phonon, electron spin-electron, or nuclear spin interactions. If a narrow-band laser is tuned on the $S_0 \leftarrow S_1$ electronic transition and if its power is kept sufficiently low to avoid saturation, the width of the observed transition of a chromophore, called the homogeneous linewidth Γ_{hom} , is given by $\Gamma_{\text{hom}} \approx 1/\pi T_2$. The overall absorption profile results from the superposition of many homogeneous lineshapes and is called an inhomogeneously broadened absorption band. The resulting width of the convolution of the inhomogeneous distribution function with the function describing the homogeneous lineshape is called the inhomogeneous linewidth Γ_{inh} .

For an isolated chromophore, the energy difference between the ground state and the excited state is well defined. In a solid matrix, the description of the ground and excited states of the system must include the presence of phonons that possess energies in the 10–1000 cm^{-1} range. Thermal motion at room temperature ($kT \sim 300 \text{ cm}^{-1}$) has enough energy to excite a large number of phonons. Electronic spectra then consist mostly of phonon sidebands, thus appearing to be broad and without sharp lines. At very low temperatures, narrow zero-phonon (0–0 bands) lines become observable and the spectral linewidths approach the ultimate lifetime-limited value, the so-called natural linewidth equal to $1/\pi T_1$. For typical excited-state lifetimes in the tens of nanoseconds range, the linewidth is equal to a few megahertz.

Whenever the environment of a chromophore undergoes a structural change, a spectral line undergoes a spectral jump leading to spectral diffusion. This

phenomenon can occur, for example, during rearrangements in bistable regions of glasses or polymers, following a proton transfer if the chromophore becomes engaged in a hydrogen bond or during the conformation change of a protein. The timescale of structural changes extends from less than a microsecond to nearly infinity.

Different mechanisms govern spectral hole burning in a condensed phase. In photochemical hole burning, a reaction is induced in the excited state of a photoexcited subset. New absorption features of a photoproduct then appear outside the inhomogeneously broadened linewidth. The optical transition energy depends on the crystalline environment in a complicated way, and the hole-burning laser is not selecting molecules in a specific environment, but a subset of molecules in different environments absorbing at its frequency. The photoproduct band (antihole) is thus, in general, broader than the hole; the same relationship between transition energy and environmental parameters does not hold for the photoproduct. Photoredox, ligand exchange, tautomerization, and conformer interconversion are among the possible photo-induced reactions. In proteins, for example, three amino acids (tryptophan, tyrosine, and phenylalanine) possess aromatic residues and can thus act as intrinsic UV chromophores. The reaction used in photochemical hole burning of tyrosine involves the transfer of the O-H proton to a neighboring acceptor. The excited-state dynamics of the chromophores of the green or red fluorescence proteins (GFP or RFP), widely used in living cell imaging, have been investigated by low-temperature (1–4 K) hole-burning spectroscopy. Pigments such as chlorophylls and reactive centers of photosynthesis can also be used as optical probes to study charge separation and energy transfer by means of hole-burning studies.

Nonphotochemical hole burning can occur in organic or inorganic amorphous and crystalline systems. Following the selective excitation of a subset of chromophores, rearrangements (such as hydrogen bonds, translations, or rotations of chemical groups) of host-guest interactions can take place and lead to absorption features still falling in the inhomogeneous linewidth.

Applications of Hole-Burning Spectroscopy

Spectral hole burning is not only a powerful tool for studying electronic structure of molecules and ions, but it also has many potential applications in the use of spectral holes as frequency references, in all-optical spectrum analyzers and quantum computing. Among the most promising applications are probably frequency-domain and time-domain high-density storages of digitized information as large as $10^{14} \text{ bits cm}^{-3}$. For applications,

materials are often characterized by the figure of merit $\Gamma_{\text{inh}}/\Gamma_{\text{hom}}$. Typical ratios between inhomogeneous and homogeneous bandwidths are in the order of 10^3 – 10^4 for molecular doped organic or inorganic glasses, whereas it can reach up to 10^9 for Eu^{3+} ions doped crystals cooled down to liquid helium temperature.

Hole burning can be achieved during short amounts of time or quasi-permanently. In transient spectral hole burning, the depletion of the ground state of a photo-excited subset lasts as long as the chromophores take to relax to their initial ground-state level. This relaxation time can be the very short excited-state lifetime if the system only possesses the excited and the ground states. On the contrary, it can become very long if the excited state relaxes toward a metastable state situated immediately below it. Many applications rely on persistent spectral hole burning. The hole-burning laser is first kept at constant frequency for a certain period of time and can further be slewed across the inhomogeneous profile to reveal the dip in the absorption/excitation spectrum. The hole-burning and readout processes can be undertaken on a slow timescale. On the contrary, laser diodes can be slewed over 30 GHz on the nanosecond–microsecond timescale by changing the injection current.

Gratings can be engraved in a spectral hole-burning material. Those gratings are quasi-monochromatic and each of them is able to diffract a single spectral component, with a resolution ultimately determined by the homogeneous linewidth of the used material medium, which is usually less than 1 MHz at the temperature of 5 K. A large number of gratings can coexist within the inhomogeneous width of the absorption line, which may reach tens of gigahertz.

This allows a different approach to holography. In spatial holography, the first step is the production of a spatial interference pattern between a reference beam and an object beam. Once the object is removed, the reference beam is used to read the hologram; it diffracts off the grating in the holographic plate, thus creating a replica of the object. In spectral hole-burning materials, interference can take place in frequency domain. When the frequency-domain amplitudes of an object pulse and a reference pulse are combined in a frequency-selective medium, the resulting intensity contains a frequency-domain interference pattern. The readout procedure is similar to conventional holograms. The object beam is terminated and the hologram is illuminated with a replica of the reference beam. By virtue of Fourier transformation, this allows one to record and play back optical signals in the time domain. In frequency-selective material, the limit of time resolution comes from the finite inhomogeneous broadening bandwidth of the recording material. Generally, the temporal resolution is less than 100 fs and this allows the possibility of femtosecond holography.

Quantum computing relies on the use of coherent superposition of states called qubits, in contrast with usual digital computers where digits exist only in either a 0 or a 1 state. A crucial problem encountered in the realization of qubits is the decoherence time between entangled quantum states. Metastable ground-state hyperfine levels of rare earth ions labeled $|0\rangle$ and $|1\rangle$ are coupled by optical transitions to an excited state $|e\rangle$. This excited state $|e\rangle$ is inhomogeneously shifted by up to several gigahertz, whereas the homogeneous linewidth of the optical transitions can be as low as a few kilohertz. It is then possible to address a very large number of frequency-selected subensembles of ions identified by their inhomogeneous shift, each subensemble being separated from the broad inhomogeneous profile by spectrally hole burning an interval around its own frequency. Narrow structures in frequency space can then be addressed by laser fields. The optical frequency is used to selectively perform quantum gates on the individual qubits, that is, drive transitions between the qubit levels $|0\rangle$ and $|1\rangle$ via the excited state $|e\rangle$. For example, Ce^{3+} ions in a YPO_4 matrix possessing a homogeneous linewidth of their 4f–5d transition of approximately 50 MHz and a 5d state lifetime of approximately 20 ns have been proposed as candidates for the realization of elementary registers of quantum computers.

Introduction

Much of our information on the microscopic features of matter in various aggregate states has been obtained from spectroscopy. How detailed such information can be depends on the resolution of the experiment. During the evolution of modern physics it often happened that theory predicted features that could not be verified experimentally because the resolution of the associated spectroscopic techniques was too low. As an example, consider the famous experiment by Pound and Rebka in 1960 by which the gravitational red shift of an electromagnetic wave could be verified. This red shift was predicted by Einstein in 1911 on the basis of general relativity, but the verification had to wait until there was a technique available with the necessary resolution. The required resolution is incredibly high, of the order of 10^{15} , but, nevertheless, could be achieved by making use of the Mössbauer effect. A resolution of 10^{15} means that the frequency of an electromagnetic wave of 10^{15} Hz can be determined with an accuracy of 1 Hz. The highest resolution that can be achieved in the spectroscopy of a particular system (e.g. of atoms, molecules, nuclei, etc.) is

determined by the natural width of the spectral lines in these systems. According to the Heisenberg principle, this width is determined by the lifetime of the excited state. However, in almost all real systems this ultimate limit cannot be achieved in a straightforward way because the environment of the system broadens the respective levels. The Mössbauer effect is one technique where the natural line width can be exploited for high-resolution spectroscopy. Hole burning techniques also work at this ultimate limit of resolution, but the physical principle is totally different. Nevertheless, because of the ability to do spectroscopy at the limit determined by the natural line width, the hole burning technique is sometimes called the ‘optical Mössbauer effect’. The following surveys how the hole burning technique evolved during the last few decades of the twentieth century, its physical basis, and the fields of spectroscopy and technology in which it is used.

Hole Burning: A Survey

Hole burning stands as a generalized synonym for all kinds of saturation spectroscopic techniques in inhomogeneously broadened bands. At the frequency where saturation is performed, a dip appears in the spectrum, the so-called hole. Generally speaking, the hole burning technique aims to unravel the features of the homogeneous line shape of the transition involved, which is obscured by the presence of strong inhomogeneous broadening. Hole burning was demonstrated for the first time in 1948 in NMR spectroscopy. Since then, it has been used in almost all fields of spectroscopy: NMR, EPR, dielectric, IR and optical spectroscopy. Hole burning experiments have been applied to almost all aggregate states: gases, liquids, crystals, glasses and polymers. More recently biological materials have also attracted increasing interest.

The power of the technique rests with a special variation of hole burning, so-called persistent spectral hole burning. Persistent spectral hole burning was discovered in 1974 by Gorokhovskii, Kharlamow and their respective co-workers. It is based on population storage in a long-lived intermediate, which is very often a photochemical state. In this case the method is called photochemical hole burning. It is the persistence of the holes that has made the hole burning method an

important and attractive technique in a very broad field of spectroscopy techniques and applications. The application to optical data storage in the frequency domain, with the possibility of increasing the bit density beyond the diffraction limit, has attracted much interest. Information storage in the time domain is also a promising field of application. In addition, hole burning is a technique highly suited to storing multiple holograms in narrow frequency domains. Spectral holes can be exploited for frequency stabilization of laser radiation and for shaping of laser pulses as well as for ultra-narrow optical filters. In spectroscopy, the method has gained most attention in optical spectroscopy of the solid state. The following survey focuses on this field of study.

The Homogeneous Line Shape Function: The Perfect Crystal Case

Consider an optical transition of a dye probe molecule doped at a low concentration into a perfect crystal lattice (Figure 1a). Since all the probes have the same local environment, their absorption frequencies coincide and the line shape of the transition considered is representative of the line shape of a single probe molecule. Excitation of the probe molecule is accompanied by a charge redistribution in the excited state. This leads to a different equilibrium configuration of the lattice molecules in the excited state. As a consequence, there is a certain probability that the optical excitation will be accompanied by excitation of lattice motions that give rise to so-called phonon side bands. The intensity distribution is determined by the Franck–Condon principle. The relative intensity of the transition with no lattice phonon excitation, the so-called zero-phonon line, is given by the Debye–Waller factor α :

$$\alpha = \frac{\text{Intensity in zero-phonon line}}{\text{Total intensity in the band}}$$

As a rule, the zero-phonon line is much narrower than the accompanying phonon transitions. Consequently, its peak intensity is much higher than the peak intensity of the phonon wing (Figure 1b). The reason for the large line width of the transitions into phonon states is the short lifetime of these states, which is largely determined by vibrational relaxation.

In comparison with the phonon states, the lifetime T_1 of the purely electronic state can be orders of magnitudes longer. According to the Heisenberg law, the width $\Delta\omega_0$ of the zero-phonon line is given by

$$\Delta\omega_0 = \frac{1}{T_1} \quad [1]$$

$\Delta\omega_0$ is called the natural width of the transition. As a rule, the transition attains this width only at very low

Figure 1 (a) Sketch of a perfect host lattice (honeycomb) doped with probe molecules (black bars). (b) Line shape of an ensemble of identical probe molecules in a perfect host lattice.

temperatures, i.e. at around or below a few kelvin. At higher temperatures, the line width is determined by the thermal fluctuations of the lattice, which lead via some coupling mechanism to thermal fluctuations of the energy levels involved, i.e. of the electronic ground and excited states. Since these fluctuations disrupt the phase of the polarization, they are called dephasing processes. The decay time T_2^* of the phase coherence is called the pure dephasing time. These dephasing processes provide an additional contribution to the line width, so that the total line width $\Delta\omega_h$ is determined by two contribution:

$$\Delta\omega_h = \frac{1}{T_1} + \frac{2}{T_2^*} \quad [2]$$

$\Delta\omega_h$ is called the homogeneous line width. As a rule, the associated line shape is Lorentzian. As the pure dephasing contribution $2/T_2^*$ dies out rapidly as the temperature approaches absolute zero, $\Delta\omega_h$ approaches

its ultimate limit of $\Delta\omega_0$ at very low temperature. As an example, consider an organic dye molecule. T_1 is typically of the order of some tens of nanoseconds, so that $\Delta\omega_0$ is of the order of some tens of MHz. In this case the ultimate limit of spectroscopic resolution is around 10^7 .

Inhomogeneous Broadening

A basic requirement for spectral hole burning to be observed is inhomogeneous line broadening. In NMR, inhomogeneous broadening originates mainly from field inhomogeneities. In the gas phase, inhomogeneous broadening comes from the velocity distribution of the molecules, which leads to a frequency distribution via the Doppler effect. In the solid state, inhomogeneous line broadening occurs because of structural disorder. For example, in a crystal there are lattice defects that cause statistically varying strain fields. These strain fields lead to statistically varying frequency shifts of the zero-phonon transitions of the probe molecules. As a consequence, the zero-phonon frequencies are spread out and the line experiences a broadening $\Delta\omega_i$. Whereas the homogeneous line broadening $\Delta\omega_h$ is dynamic in nature, inhomogeneous broadening is, at sufficiently low temperature, essentially static in nature.

In a more general way this situation is sketched in **Figure 2a**. Each of the probe molecules sees a different environment and hence their absorption frequencies are different.

In organic crystals, the inhomogeneous broadening is of the order of a wavenumber; in glasses it is of the order of several hundred wavenumbers. In this latter case, even the phonon side bands are largely buried beneath the inhomogeneous envelope (**Figure 2b**).

In contrast to the homogeneous line shape, which is Lorentzian, the inhomogeneous distribution is governed by the statistics of large numbers and hence is Gaussian. At sufficiently low temperatures, the ratio of the inhomogeneous to the homogeneous width may cover 5–6 orders of magnitude.

Hole Burning

Suppose the dye probe molecule is photoreactive. Then, to understand the essential features of hole burning, it suffices to consider three states only: the ground state S_0 , the first excited singlet state S_1 , and the photoproduct state P_0 (**Figure 3**). For simplicity we assume that P_0 has an infinite lifetime. The absorption spectrum of P_0 is shifted as compared to that of S_0 because P_0 represents a structurally different molecule. Consider **Figure 4**: narrow-bandwidth laser light is tuned to some position within the inhomogeneous band. We denote the respective frequency by ν_L . Excitation leads to

Figure 2 (a) Sketch of a disordered lattice doped with probe molecules (black bars). Note that each probe molecule has a different environment. (b) Inhomogeneous line broadening: the inhomogeneous line of width $\Delta\omega_i$ is built from an ensemble of homogeneous lines of width $\Delta\omega_h$.

Figure 3 Three levels are necessary for persistent hole burning. P_0 has a long lifetime and acts as a storage state.

photochemistry; hence, population is transferred to P_0 and, concomitantly, S_0 is depleted. However, depletion in S_0 can only occur in a spectral range around ν_L roughly determined by the homogeneous line width $\Delta\omega_h$. At

Figure 4 Hole burning: laser radiation with frequency ν_L creates a population dip and, concomitantly, a hole in the inhomogeneous band.

temperatures of a few kelvin, $\Delta\omega_h$ is close to $\Delta\omega_0$ and hence is extremely narrow. As a consequence, the depletion dip is extremely narrow. The depletion dip is called the 'spectral hole'. If P_0 has an infinite lifetime, the lifetime of the hole is, of course, also infinite. In this case the hole is persistent. However, in the usual terminology holes are called persistent if their lifetime is much longer than the typical hole burning timescale determined by burning and reading the hole. A typical order of magnitude for this timescale is a few minutes. For vanishingly small depletion and sufficiently low power of the burning laser, the shape of the depletion hole is Lorentzian with a width close to $\Delta\omega_h$. This depletion hole is, for instance, detected by scanning the laser over the depletion range. The resulting line shape of the recorded hole is a convolution of the depletion hole with the homogeneous line shape, i.e. a convolution of a Lorentzian with a Lorentzian that is itself a Lorentzian of twice the width:

$$\Delta\omega_H \Rightarrow 2\Delta\omega_h \quad [3]$$

where $\Delta\omega_H$ is the hole width.

Figure 5 shows a hole in the inhomogeneous absorption band of protoporphyrin IX-substituted myoglobin. The inset shows the hole on an enlarged scale.

Saturation Broadening

Saturation spectroscopy of two-level systems results in a power-dependent line width of the transition concerned,

Figure 5 A spectral hole in the absorption spectrum of myoglobin complexed with protoporphyrin IX at $T=1.5$ K.

a phenomenon termed power broadening. In a similar fashion, line broadening due to strong saturation can also occur in a three-level system with a long-lived storage state P_0 . However, in this case, it is not the power that determines the broadening but rather the number of irradiating photons, which is proportional to the irradiated energy dose or to the laser fluence. Hence, we call this broadening 'fluence broadening'. It is easy to see why the irradiated energy and not the power is the important factor: the power needed to burn a hole with a certain depth can be made arbitrarily small by increasing the irradiation time accordingly. This has no effect on the hole area so long as P_0 has an infinite lifetime. However, if the irradiated energy increases, photochemistry in the centre of the line slows down because the number of absorbers decreases, but it is still going on in the wings. As a consequence, the centre of the line is more strongly depleted and the line flattens and becomes broader. Because of this saturation broadening, the homogeneous line width must be determined from a plot of the hole width as a function of laser fluence in the limit of vanishing fluence. Likewise, one can plot the hole width as a function of the hole depth (**Figure 6**): as the depth approaches zero, the hole width converges to $2\Delta\omega_h$.

Hole Burning Techniques

The deeper the holes, the better is the signal-to-noise ratio. However, deep holes are artificially broadened owing to saturation. Hence, techniques have been developed for reading shallow spectral holes with a high signal-to-noise ratio.

The most straightforward way to read a hole is to scan the laser over the frequency range where burning has been performed. In the range of the hole, the number of

Figure 6 Saturation broadening due to laser fluence. Reproduced with permission from Dick B (1989) Habilitationsschrift, University of Göttingen.

absorbers is diminished and so there is an increased transmission. The transmission technique requires a baseline correction since the hole is detected on top of an inhomogeneous background absorption. For an optical density around 1, relative transmission changes of a few per cent can easily be detected in this way.

If the optical density at the burning frequency is well below 1, the fluorescence excitation mode is more appropriate for reading the hole. In this mode it is not the transmission but rather the fluorescence that is measured. If the laser is scanned across the spectral range of the hole, the fluorescence decreases. The relative change of the fluorescence as a function of frequency directly follows the shape of the hole. A baseline correction is required in this case, too.

There are some elaborate techniques that are extremely sensitive because they are based on zero-background signals. The most important of these are the dichroitic and the holographic techniques.

In the dichroitic technique, the hole is burnt with a polarized laser field, say in the z direction (**Figure 7**). The polarized laser radiation leads to an anisotropic distribution of the vector N , denoting the number density of absorbers oriented with their transition dipole moment at an angle θ to the polarization of the burning field. Reading is performed with the sample between two crossed polarizers P_1 and P_2 , inclined at say -45° and $+45^\circ$ to the z direction. If the sample is isotropic, it does not alter the polarization direction, so the reading laser field E_1 will be P_1 -polarized and will be blocked by P_2 . On the other hand, if at frequency $\nu - \nu_L$ the sample has a preferred transmission for z -polarized light, then the reading laser field E_1 will be

Figure 7 Exploiting the dichroism of holes for a low-noise reading process. N denotes the number density of absorbers with their dipole moments in the direction θ . P_1 is the polarizer, P_2 the analyser.

rotated towards the z axis. As a consequence, the respective field vector E_1' will acquire a component E_2' along the P_2 direction and light will be transmitted. In this way the hole is measured against zero background intensity. Accordingly, the signal-to-noise ratio can be orders of magnitude better than with the transmission or fluorescence detection modes and tiny changes in optical density can be measured. However, two things have to be accounted for: the degree of anisotropy is not constant over the frequency range of the hole, and it also depends on the depth of the hole. This so-called polarization bleaching is very similar to saturation broadening. For strong polarization bleaching, the shape of the hole may be flattened or may even show a double peak structure. Apart from this effect, the hole shape may also suffer from interference with light which is not totally blocked by P_1 and P_2 as a result of small degrees of misalignment.

In the holographic technique two beams, 1 and 2, interfere at an angle of 2θ in the sample and write a spatial grating of the absorption coefficient and of the index of refraction (**Figure 8**). The modulation of this grating is frequency dependent via the line shape function. If one of the writing beams, say 2, is blocked, the other beam can serve as the reading beam. If it is tuned across the frequency range of the hole, the grating deflects the reading beam (1) into the direction of beam 2. The intensity of the diffracted light is proportional to the modulation depths of the absorption coefficient and of the index of refraction, and hence is strongest at the centre of the hole and vanishes far in the wings. Although the holographic technique reproduces the true line shape of the hole as long as the saturation of the hole is weak, it has characteristic properties that have to be taken into account. First, strong bleaching results in a strong deviation from a sinusoidal grating, which leads to higher diffraction orders. Second, strong bleaching also leads to a strong distortion of the Lorentzian line shape, which may eventually show a double peak structure.

Figure 8 Holographic hole burning: burning is performed via two beams, 1 and 2, which interfere in the sample and create a spatial grating $I(x)$ of the absorption coefficient and the index of refraction.

Applications of Hole Burning

Spectroscopy

Hole burning has been used in a very broad field of scientific problems ranging from solid-state physics to biological physics. The most straightforward application is the measurement of the homogeneous line width. Apart from measuring vibrational relaxation in the excited electronic state in this way, most effort has been put into measuring the homogeneous line width of the purely electronic $S_1 \leftarrow S_0$ absorption of dopant molecules in glasses. The homogeneous line width in a glassy host material has quite specific properties compared to that in crystalline materials (**Figures 9a** and **b**): in the low-temperature regime, $T < 4$ K, the homogeneous width in a glass is an order of magnitude larger than in a crystal (**Figure 9a**). In a crystal, it is already close to its lifetime-limited value and hence is temperature independent (**Figure 9b**). In a glass, it depends on temperature down to the lowest temperatures measured in these types of experiments (~ 50 mK); however, its temperature dependence is weak. It is usually well described by a temperature power law $\sim T^\alpha$ with α between 1 and 2. In a crystal, the temperature dependence goes as T^7 or is very often activated. The reason for the specific features of the optical line width in glasses is the presence of specific degrees of freedom, so-called TLS (two-level system) modes, which reflect the disorder in the structure and which cannot be frozen out, not even at the lowest temperatures reached so far in solid-state materials.

The TLS degrees of freedom reflect the simplest approach to characterizing the complex energy landscape of disordered materials such as glasses and polymers. These materials are never in true thermodynamic equilibrium, and, hence, there are always some structural

Figure 9 (a) Hole widths of chlorine-doped benzophenone glass (broad hole) and crystal (narrow hole). (b) The homogeneous line widths of chlorine-doped benzophenone glass and benzophenone crystal as a function of temperature. Note the different scales for glass and crystal.

Figure 10 Spectral diffusion broadening as a function of waiting time t_w for different ageing times. The sample is protoporphyrin IX in a dimethylformamide/glycerol glass; temperature is 100 mK. Inset: Broadband absorption spectrum. The arrow marks the wavenumber where hole burning was performed.

Figure 11 Deformation of a spectral hole in an external field. The external field E_{st} (about 12 kV cm^{-1}) is parallel to the laser field. The sample is protoporphyrin IX-substituted myoglobin in a glycerol/water glass. The double peak structure is indicative of a chromophore with a well-defined dipole moment.

dynamics covering an extremely broad range of relaxation rates of up to 15 orders of magnitude, from nano-seconds to months. These structural dynamics create locally fluctuating strain and/or electric fields that, in turn, lead to fluctuations of the electronic energy levels of the dye probe. These fluctuations are reflected in a time-dependent line broadening, called spectral diffusion (Figure 10). Measurement of the spectral diffusion broadening gives insight into the structural dynamics and the associated features of the energy landscape. This is especially interesting for biological materials.

Another major field in which the hole burning technique can be exploited concerns measuring the influence of external fields, such as electric, magnetic or pressure

Figure 13 Hole burning via nuclear spin conversion in rotational tunnelling states of methyl groups. The sample is dimethyl-s-tetrazine in *n*-octane at 1.4 K. The central hole at the laser frequency is accompanied by two antiholes symmetrically shifted by 37 GHz.

Figure 14 The level scheme of a methyl rotor attached to a chromophore. δ and δ^* are tunnelling splitting in S_0 and S_1 , respectively. T_1 is the lowest triplet state. fields, on the electronic energy levels. For instance, measuring the Stark effect (electric field) even in good-quality crystals usually requires special modulation techniques since the spectral changes are rather small. In disordered materials, owing to the large inhomogeneous broadening, it is difficult to obtain good-quality data unless unusually large changes of the dipole moments are involved. In hole burning, moderate field strengths (10 kV cm^{-1}) and pressure levels (1 MPa) yield easily detectable line shifts and field-induced changes in the line widths. Moreover, the high resolution and the associated selectivity of these experiments enable one to investigate field effects as a function of frequency within the inhomogeneous band. The solvent shift can be varied simply by tuning the laser frequency and hence becomes a parameter of the experiment. From hole burning Stark effect experiments (Figure 11), information on the molecular dipole moments involved, on the respective

polarizabilities, on matrix fields and on associated symmetries can be obtained. High-quality quantum chemical calculations are usually desirable to support the interpretation of the experiments because there are always several parameters that are not very well known. From pressure experiments (Figure 12), information on local compressibilities, on molecule–matrix interactions and on the vacuum absorption frequency of the probe molecule can be obtained.

Hole burning has been used widely to investigate relaxation processes of coherent tunnelling in the solid state. An outstanding example in this context is the methyl group. Consider a dye probe molecule with one or several methyl groups attached, for instance dimethyl-s-tetrazine (Figure 13). Irrespective of how disordered the host matrix is, the methyl group always has at least a threefold rotational symmetry axis (along the C–C bond), which results in a threefold periodic potential $V = V_3 \cos 3\varphi$, where φ is the angle of rotation around the C–C bond and V_3 is the barrier height. The lowest states in this potential interact via the tunnelling interaction. As a result, the three states form a split pair, with A and E symmetry, where the E state is still doubly degenerate. Since the C_3 group is isomorphic to the group of even permutations of the protons, the wavefunctions of the methyl rotor have to be totally symmetric according to the Pauli principle. Relaxation between the tunnelling states requires an interaction, which breaks the permutation symmetry. These interactions necessarily contain the nuclear spin, and so are very small. Accordingly, the lifetimes of these states can be extremely long (e.g.

months at 1 K) and thus population can be stored in these states. This is where hole burning comes in. Suppose laser light excites a molecule in its A-rotor (E-rotor) state from S_0 to S_1 (Figure 14). From S_1 , intersystem crossing to the triplet state T_1 occurs. In the T_1 state the electron spin turns around the nuclear spin via the hyperfine interaction; the rotor converts from the A to the E state

Figure 15 Rotational tunnelling relaxation rate as a function of temperature in a log–log representation. Fitted curves are based on Raman-type relaxation processes. Note that the tunnelling relaxation in the deuterated rotor is faster by two orders of magnitude. The sample is dimethyl-s-tetrazine in *n*-octane.

Figure 16 (a) Hole burning and data storage. (b) In each spatial spot many bits can be stored in the frequency or wavelength domain. The dye probe, in this case, is quimizarin whose structure is shown in the inset.

or from the E to the A state. Light irradiation thus creates a population redistribution among the rotational tunnelling states. The point is that this population redistribution is accompanied by a frequency transformation because the tunnelling splitting δ^* in S_1 may be different from that in S_0 . Hence, a hole appears at the laser frequency, which is accompanied by two antiholes shifted symmetrically by the difference $|\delta - \delta^*|$ between the tunnelling splitting in S_0 and S_1 (Figure 13). The hole offers an easy way to measure the rotational tunnelling relaxation. All one has to measure is how the hole recovers or how the antiholes vanish. Figure 15 shows the tunnelling relaxation rate as a function of temperature for the protonated and the deuterated rotor. The rate increases with T^7 , indicating a Raman-type relaxation process. Deuteration speeds up the relaxation instead of slowing it down because of the nuclear quadrupole interaction associated with the deuterons and the fact that the methyl rotor in the example considered is almost free.

Summarizing the application of hole burning in spectroscopy, it should be noted that there is also a large field in which it is used in elucidating photochemical reactions. It is also increasingly used in studies of photosynthesis, to shed light on the energy and electron transfer processes, on the nature of the states involved, on electron phonon coupling and exciton coherence. Further, the hole burning technique offers great power to investigate the features of the energy landscape of proteins and the associated dynamics in conformation space.

Technology

In 1976 the use of hole burning was suggested for frequency-domain optical data storage. Figure 16 sketches the principle. The storage medium could, for instance, be a dye-doped polymer film. In each spatial spot (Figure 16a) a number of about $\Delta\omega_i/\Delta\omega_H$ bits can be stored in the frequency domain (Figure 16b), with $\Delta\omega_i$ being the inhomogeneous width and $\Delta\omega_H$ the hole width. $\Delta\omega_i/\Delta\omega_H$ could be as large as 10^4 – 10^5 . As a consequence, the capacity of an optical storage device could be increased by several orders of magnitude beyond the diffraction limit, i.e. to about 10^{12} bits cm^{-2} . So far such a memory has not been realized because too many requirements have to be met simultaneously: the high bit density is achieved only at liquid helium temperatures; at higher temperatures the information is, at least partly, lost; appropriate dye molecules should absorb in the frequency range where common laser diodes work; the respective Debye–Waller factors as well as the photochemical yields should be high so that information can be written and read in the nanosecond time regime; and repeated reading may deteriorate the stored information.

Solutions could be found for many of these requirements. For instance, the use of photon-gated hole burning ensures nondestructive read out. Many materials have been discovered in which this concept could be successfully demonstrated; however, attempts to unify all the requirements in one system have failed so far.

Instead of storing data bits in the frequency domain, they can be stored in the time domain, for instance as a pulse sequence E_S as shown in Figure 17a. Writing of the information is performed by interference of the signal E_S with a short reference pulse E_R in the photochemical storage material. If the spectral width of the reference pulse E_R is much larger than the width of the whole signal train E_S , which in turn is much larger than the homogeneous width of the respective optical transitions of the storage material, then the whole Fourier spectrum of the signal train can be stored as a grating in frequency space, i.e. as many holes in the inhomogeneous band whose width, of course, has to be even larger than the width of the reference pulse. Figure 17b demonstrates how the stored information is recovered. If a single pulse E_R hits the sample some time (hours, days, weeks) later, the sample regenerates the whole pulse sequence. Depending on how the reference pulse is applied in the writing and reading procedure, the time-reversed signal train can be generated as well. This is nothing other than

Figure 17 (a) Data storage in the time domain using the 'PASPE' technique. (b) Reading the information. The echo is stimulated by a single pulse.

Figure 18 Five holograms stored as holes in the electric field domain. By scanning the field, the five holograms can be read out serially, resulting in a movie showing a running jogger. a special form of the stimulated photon echo where the contrast of the stored information can be enhanced by accumulating the information over many writing cycles in the long-lived photochemical state. Accordingly, the technique has been called PASPE – photochemically accumulated stimulated photon echo.

As well as storing information bitwisely, it is also possible to store information in an analogue fashion as a hologram of a picture. The concept is very similar to that shown in **Figures 17a** and **17b**, but with E_R and E_S being the reference and the object waves, respectively. The reference wave can, for instance, be a plane wave. The object wave carries all the information of the picture. The two waves interfere for some time in the storage medium and create a hole at the laser frequency. In the frequency domain this hole is sharp, but in space it is distributed over a larger part of the storage material. Again, one can store many holograms in the frequency range covered by the inhomogeneous band. The holograms can be read by scanning the reading laser beam over the frequency interval where the holograms are stored. If the reading laser beam is directed along the direction of the reference beam, the burnt-in hologram regenerates the original object wave. Likewise, reading can be performed in the electric field domain by making use of the Stark effect. In this case the holograms are stored with an electric field applied in a way that each hologram has its own specific Stark field. The frequency of the burning (and reading) laser is fixed. In reading the

holograms, the Stark field is tuned. Whenever the field reaches one of the specific values used during the storage process, a holographic interference pattern with a spatially well-resolved modulation of the absorption coefficient and index of refraction appears that scatters the light from the reading laser such that the object wave is regenerated. **Figure 18** shows an example: five pictures are stored as holograms in the five holes shown. Since each hole has its specific Stark field, reading is performed by scanning the electric field. In this way, a movie is generated, showing a jogger, as indicated in the figure.

Introduction

High-performance liquid chromatography (HPLC) has become a routine tool for the separation of complex mixtures. However, structural information on substances separated using HPLC is limited by the detector system employed. The most common HPLC detectors, refractive index, UV (ultraviolet), radiochemical, fluorescence, and electrochemical, provide little or no structural information. As a result, structure elucidation required the isolation of

the analyte from the matrix, followed by off-line spectroscopic characterization. With the advent of HPLC–MS (mass spectrometry), the ability to detect and identify substances at low concentrations without the need for an isolation step became possible. Although this has simplified structure elucidation to a great extent, there are often circumstances where HPLC–MS alone is insufficient for complete characterization of a compound and further studies by nuclear magnetic resonance (NMR) are required. Logically, the next step in instrument development would be directly coupling HPLC and NMR yielding the hyphenated technique HPLC–NMR.

History

In the late 1970s and early 1980s, a number of attempts to couple these techniques were carried out. However, these studies suffered from the low sensitivity of the NMR spectrometer systems then available. Also, because of dynamic-range problems, there was a need to use expensive deuterated solvents for the HPLC because the solvent suppression methods in use at that time could not cope with fully protonated solvents. The reduction in HPLC–NMR to routine use was slow in developing and not practically achieved until technical improvements in electronics, higher magnetic fields strengths, advanced solvent suppression sequences, and improved instrumental sensitivity made it feasible to interface an HPLC directly to an NMR spectrometer.

In addition, investigations into coupling other types of chromatography with NMR have been carried out. These include capillary electrophoresis, capillary electrochromatography, supercritical fluid chromatography, and capillary HPLC. However, there are no commercially available systems based on these separations.

Technical Improvements

There have been many major technical improvements in NMR sensitivity in recent years. Foremost has been the development of ultra-high-field-strength magnets. High-dynamic range analog-to-digital converters (ADCs), which give benefits in situations where large solvent peaks are present along with small analyte signals, and digital filtering techniques that allow spectral windows to

be limited to include only the region of interest, without the problem of signals and noise from outside this spectral region folding in, have also contributed to increases in sensitivity. Another important improvement is oversampling. That is, the collection of digital data points at a rate faster than that required to satisfy the Nyquist criterion of twice the highest desired spectral frequency. In theory, for an oversampling factor of n , a gain in dynamic range of $\log_2(n)$ is obtained, that is, for an oversampling of eight times, an effective gain of 3 bits in ADC resolution of the signals results. In practice, the oversampled signal is simply averaged over the n measurements to restore the same number of data points corresponding to the Nyquist criterion. This prevents folding of noise or artifacts that would have been in the extended spectral region, resulting from a consequence of the oversampling being equivalent to a spectral region n times wider than required to satisfy the Nyquist criterion. Thus, a second consequence of oversampling is an improved signal-to-noise (S/N) ratio from removal of folded noise when the spectral region is truncated.

The HPLC-NMR System

A block diagram of a typical instrumental setup for HPLC-NMR is shown in **Figure 1**. This comprises a high-resolution NMR spectrometer with its superconducting magnet into which is placed a dedicated NMR flow probe, a standard HPLC system controlled by PC-resident software, and a flow control unit that enables the system to be operated in four main modes as listed in the following text.

- On-flow
- Stop-flow
- Time-sliced stop-flow
- Peak collection into capillary loops for post-chromatographic analysis.

The simplest method of operation is continuous-flow detection. This mode of operation is generally only feasible when using ^1H or ^{19}F NMR for detection unless enriched compounds are used. If on-flow detection is required during a solvent gradient elution, the NMR resonance positions of the solvent peaks will shift as the solvent proportions change. For effective solvent suppression, it is therefore necessary to determine these solvent resonance frequencies as the chromatographic run proceeds. This is accomplished by measuring a single exploratory scan as soon as a chromatographic peak is detected in real time during the chromatographic run and then applying solvent suppression irradiation at these frequencies as the peak elutes. The data from an on-flow experiment performed on a sample of human urine after dosing with paracetamol [1] are shown in **Figure 2**. The

data are plotted in a pseudo-2-D format with the axes being the chemical shift in part per million and the retention time of the chromatographic run. Slices extracted from the 2-D plot show the 1-D spectra of the glucuronide [2] and sulfate [3] conjugates of paracetamol (**Figure 3**).

[1] Paracetamol

[2] Glucuronide conjugate of paracetamol

[3] Sulfate conjugate of paracetamol

If the retention times of the compounds to be separated are known, or if they can be detected using refractive index, UV (including diode arrays), radiochemical, or fluorescence detectors, stop-flow HPLC-NMR becomes

Figure 1 Block diagram of a typical HPLC-NMR system.

Figure 2 Pseudo-2-D plot of on-flow ^1H HPLC-NMR data obtained on human urine after dosing with paracetamol [1]. The resonances from the glucuronide [2] and the sulfate [3] conjugate metabolites of paracetamol are indicated.

an option. Upon detection the PC controlling the liquid chromatograph allows the pumps to continue running, moving the peak of the interest into the NMR probe. Once the pumps have stopped, normal high-resolution NMR is possible. It could be argued that the long length of capillary tubing connecting the HPLC system to the NMR probe will cause a significant loss of resolution in the separation. In fact this is not a problem. The NMR detection cell volume is typically 60–120 μL , and this represents the limiting factor in the chromatographic

resolution. The practicality of the stop-flow approach has been amply demonstrated, and although several separate stops are often made in each chromatographic run, the quality of the resulting NMR spectra is such that good structural information can be obtained. Even long 2-D experiments, which provide correlation between NMR resonances, based on mutual spin-spin coupling such as correlation spectroscopy (COSY), total correlation spectroscopy (TOCSY) and heteronuclear correlation studies such as heteronuclear multiple quantum coherence

Figure 3 One-dimensional slices extracted from the on-flow experiment shown in **Figure 2**. The top trace is the sulfate conjugate [2] and the bottom trace is the glucuronide conjugate [3].

(HMQC) spectroscopy can be performed. It is in this stop-flow mode that HPLC-NMR is most commonly used.

There are two further special categories of stop-flow experiment. These comprise the ability to store eluting fractions in capillary loops for later off-line NMR study ('peak picking') and the very useful ability to stop the flow at short intervals over a chromatographic peak to 'time slice' different parts of a chromatographic run. This is analogous to the use of diode-array UV spectroscopy to obtain spectra from various positions within an eluting peak to determine peak purity. The time-slicing methods may be useful if there is poor chromatographic separation, if the compounds under study have weak or no UV chromophores or if the exact chromatographic retention time is unknown. It is also possible to time slice through an entire chromatographic run producing the equivalent of an on-flow experiment with higher signal to noise. The data from such a time-slicing experiment have been referred to as a total NMR chromatogram (tNMRC).

In all the modes described earlier, programmed gradient elution profiles can be performed and no compromise needs to be made in the chromatographic conditions, with the exception of those outlined in the following section.

HPLC-NMR Solvents and Chromatographic Considerations

Another major problem in development of HPLC-NMR involved the use of deuterated solvents. Conventional

high-resolution NMR spectroscopy routinely uses deuterated solvents. However, these solvents are thought to be prohibitively expensive if they have to be used for elution in HPLC-NMR because of the volumes involved. It is always possible to use solvents such as CCl_4 , which contain no protons, for normal-phase chromatography, but this then requires the use of HPLC-NMR probes that have a separate external deuterium lock channel. Since most chromatographic methods are reverse phase, they involve the use of H_2O and an organic solvent such as acetonitrile or methanol. These give rise to large signals in the NMR spectrum that can obscure the spectrum of the analyte. The solution to this problem is solvent suppression that can be performed quite efficiently on modern NMR spectrometers. So efficiently, in fact, that the use of deuterated solvents is no longer a necessity. However, D_2O is used rather than H_2O to make the multiple solvent suppression easier and to serve as the field-lock substance. The cost of D_2O is relatively modest.

One of the most common organic solvents used in reverse-phase HPLC separations is acetonitrile, which gives rise to a singlet resonance in the ^1H NMR spectrum at about δ 2.0. This singlet and that arising from residual H_2O in D_2O can be easily suppressed by presaturation. However, these suppression methods based on presaturation leave the ^{13}C satellite peaks from the 1.1% of molecules with the naturally abundant ^{13}C isotope at the methyl carbon. These satellite peaks are often much larger than the analyte peaks of interest in an HPLC-NMR study and so it is often necessary to suppress these also. This has been

achieved in two ways. It is possible to set the suppression irradiation frequency over the central peak and the two satellite peaks in a cyclic fashion or, if an inverse-geometry probe is used, which includes a ^{13}C coil, then ^{13}C decoupling is possible. This will collapse the satellite peaks under the central peak, enabling conventional single-frequency suppression. The Water suppression Enhanced through T_1 effects (WET) solvent suppression method incorporates selective radio frequency (RF) pulses, pulsed-field gradients and optional ^{13}C decoupling to provide a robust solvent suppression method well suited to HPLC-NMR. **Figure 4** shows an example of WET solvent suppression on the ^1H HPLC-NMR spectrum of the desmethyl-glucuronide conjugate of naproxen [4] from human urine. The top trace shows the unsuppressed spectrum, whereas the bottom trace shows the same sample with WET solvent suppression.

Use of a fully deuterated solvent system, acetonitrile- d_3 and D_2O , is also an option when looking at very small quantities of material with resonances in the region near δ 2.0. Although the cost might seem to be prohibitive, at approximately \$1500 per liter for acetonitrile- d_3 , the solvents for a typical HPLC run using both D_2O and acetonitrile- d_3 cost only \$12–15.

Other chromatographic considerations, outlined in the following text, should be considered when designing an HPLC separation method.

- Use buffers that have as few ^1H NMR resonances as possible.
 - Trifluoroacetic acid.
 - Ammonium phosphate.

- Ammonium acetate.
- Deuterated formic acid (\$130 per 5 g).
- Use ionpair reagents that have as few ^1H NMR resonances as possible.
 - Ionpairs with *n*-butyl groups create four additional resonances.
 - Ionpairs with *t*-butyl groups create one additional resonance.
- Whenever possible use HPLC-gradient methods.
 - Run at a 5% change per minute maximum.
 - Use columns that will be suitable for the earlier criteria.
 - Reverse-phase C_{18} .
 - 2.0–4.6 mm diameter.

Sensitivity of HPLC-NMR

The sensitivity of HPLC-NMR and the expected detection limits have been estimated for both 1D ^1H NMR and 2-D NMR. All NMR experiments were carried out using a Bruker Avance 500 NMR spectrometer operating at a ^1H observation frequency of 500.13 MHz. The spectral data were measured using a dedicated ^1H - ^{13}C inverse-geometry HPLC-NMR probe, with a 120 μl active volume. All NMR spectra were measured at 25°C. The total probe volume including the inlet line and the outlet to waste was measured to be 800 μl . Samples were injected directly into the NMR probe and hence the tests were of probe sensitivity rather than the overall sensitivity of HPLC-NMR. The S/N ratio is

Figure 4 An example of solvent suppression using WET. The top trace shows the data with no solvent suppression and the bottom trace shows the data with WET solvent suppression applied.

defined as the peak height of a given signal multiplied by 2.5 and divided by the peak-to-peak height of the noise measured over a given spectral range of 200 Hz. Spectra were measured on a standard sample of 0.1% ethylbenzene in CDCl_3 . The ^1H S/N calculation, based on the signal for the methylene quartet at 2.7 ppm, gave a value of 237:1.

A typical organic molecule 3'-deoxy-3'-azidothymidine (AZT) [5] was used to test the absolute detection limit of the same HPLC-NMR probe. Having determined the total volume of the NMR probe system to be 800 μl , a solution containing 1 mg of AZT in 120 μl was injected directly into the probe. The solvent was 80% D_2O –20% acetonitrile. The S/N ratio was measured on the ribose H1' proton in the ^1H NMR spectrum at δ 6.2. The detection limit for this ^1H signal was defined as a signal height to peak-to-peak noise ratio of 3.0 (i.e., a S/N of 7.5 by the definition given earlier). Thus, a detection limit of 500 ng in 64 scans was calculated.

[4] Desmethyl-glucuronide conjugate of naproxen

[5] AZT

AZT [5] was also used to test the ^1H sensitivity limit for a ^1H – ^1H 2D TOCSY spectrum. A spectrum was obtained using a sample of 1 μg of AZT in 120 μl of 80% D_2O –20% acetonitrile and acquired over 4.0 h. Examination of peak volumes shows that the detection limit of this experiment for 16 h of acquisition (i.e., overnight) is approximately 500 ng.

The data acquisition parameters used were designed to ensure full T_1 relaxation so that any relative integral values would be quantitative. However, these are not the parameters, which give maximum S/N values. If the ^1H NMR relaxation times are assumed to be approximately 1.5 s, and if the data had been collected in a manner designed to yield maximum S/N (i.e., with a pulse repetition rate of approximately $1.3 T_1$), then this would result in a S/N enhancement by a factor of approximately 1.4. In addition, because of the faster pulsing rate, more scans could be accumulated in the same experimental time, leading to a further S/N enhancement factor of approximately 1.7. Thus, the overall S/N might be expected to increase by a factor of approximately 2.4. In addition, for the 2-D experiments, it is possible to halve the number of T_1 increments and extrapolate the data using linear prediction. This allows the acquisition of twice as many scans per increment for the same overall experiment time, resulting in a 1.4 increase in S/N.

These detection limits will be lowered as new technical advances in NMR become available. These include higher magnetic field strengths and the future availability of HPLC-NMR cryoprobes, probes cooled to cryogenic temperatures, which reduce the noise figure and can provide as much as a 4.0 increase in S/N.

HPLC-NMR Probe Design

The flow probe is the heart of the HPLC-NMR system. The main design criteria for such probes have been defined as follows:

- The geometry of the NMR cell should allow flow characteristics that give spectral resolution sufficient to allow spin-coupled multiplets to be resolved. This enables detailed structural elucidation to be carried out.
- NMR line broadening from magnetic susceptibility and other cell-wall effects should be avoided.
- The coil design and position should provide the highest possible NMR sensitivity.
- The achievable S/N ratio of a NMR detector is a function of a number of parameters expressed in eqn [1].

$$S/N = \gamma \cdot N I(I+1) \cdot (B_0/T)^{3/2} \cdot f \cdot (QV_s/b)^{1/2} \cdot n^{-1} \quad [1]$$

Therefore, S/N can be increased by doing the following:

- Increase the sample volume and hence the number of detected nuclei, N .
- Increase the magnetic field strength B_0 .
- Increase the filling factor, f , of the NMR coil (this is V_s/V_c , where V_s is the sample volume and V_c is the volume inside the detector coil).
- Increase the quality factor, Q , of the RF coil.

- Reduce the receiver bandwidth b .
- Operate at reduced temperature T .
- Improve preamplifiers by reducing their noise figure n .

All these are for a given nucleus with gyromagnetic ratio γ and spin quantum number I .

For HPLC-NMR probes, there is a compromise that has to be made in that the detection volume should be as small as possible to get optimum chromatographic resolution and hence this can only be compensated for by increasing the filling factor. This is achieved by fixing the RF coil directly onto the outside of the NMR cell. If this is done, it is of course not possible to spin the sample to improve magnetic field inhomogeneities. However, in practice this is not a problem because the smaller the sample volume, the better the shimming. Additionally, the use of a computer-controlled orthogonal shim sets has reduced the necessity to spin the sample by greatly improving nonspinning line shapes. One major factor in determining the sensitivity or peak heights is the observed line shape. If the peaks have wide bases, then a significant part of the signal intensity is found in this part of the peak and poor S/N results. Thus, good shimming, especially with respect to the 'hump test' (the linewidth of the chloroform ^1H NMR peak at the height of the ^{13}C satellite signals relative to that at 20% of the height of the ^{13}C satellite signals) is a prerequisite for good S/N and essential to successful HPLC-NMR operation.

In superconducting magnets, the main magnetic field is parallel to the long axis of the NMR flow cell, and the flow direction and the RF are applied to a Helmholtz coil on the side of the probe insert. This coil design has a lower Q than a horizontal solenoid coil. A horizontal coil would be preferred on sensitivity grounds, but shim systems are designed for vertical sample tubes, as normally samples are inserted vertically from the top of the magnet. The NMR flow cell fixed in a vertical position has the advantage of inducing laminar flow that helps remove air bubbles from the cell.

NMR flow cells have so far had much larger volumes than, for example, UV detection cells because of the lower sensitivity of NMR. The effects that large-volume NMR cells have on chromatographic peak dispersion have been investigated using a modified fluorescence detector. The selection of the detection volume of an NMR flow cell is a compromise between the needs of the NMR sensitivity and the HPLC resolution. Typically, the optimum detection volume is 1–5 μl when an HPLC column of $250 \times 4\text{ mm}$ is used. In contrast, the usual detected volume in a conventional NMR tube is rarely less than 60 μl . It has been shown that the NMR resonances are broadened at different flow rates using detectors with a range of volumes. At flow rates of 1 ml min^{-1} , an increase of 0.14 Hz in linewidth is

obtained only with flow cell volumes $<120\text{ }\mu\text{l}$. The broadening is due to an effective shortening of the spin-spin relaxation time, T_2 , due to flow.

$$1/T_2(\text{obs}) = 1/T_2 + 1/t \quad [2]$$

Thus, where t is the flow rate. The selection of an HPLC-NMR probe is thus a compromise between sensitivity and resolution. The two most common flow cell volumes are 60 and 120 μl , respectively. In general, the 60 μl flow cells are best for on-flow experiments and stop-flow using small-diameter columns with low flow rates. The 120 μl flow cell is more suited to stop-flow experiments using conventional HPLC columns and flow rates.

Applications

HPLC-NMR has been applied to a wide range of analytical problems. These include

- The characterization of endogenous and xenobiotic metabolites directly from a biological matrix.
- Characterization of metabolites from *in vitro* studies.
- The dynamic study of reactive metabolites.
- Characterization of natural products from complex mixtures.
- Polymer characterization.
- Characterization of reaction impurities from small- and large-scale systems.

To illustrate the utility of HPLC-NMR and provide examples of typical data from HPLC-NMR experiments, the characterization of the human urinary metabolites of the anti-HIV drug efavirenz (Sustiva) is described in the following text.

Efavirenz [6] is a nonnucleoside inhibitor of HIV-1 reverse transcriptase. The metabolism of efavirenz in rats was studied using directly coupled HPLC-NMR-MS. This hyphenated technique utilizes an eluent splitter to also incorporate a mass spectrometer into the HPLC-NMR system to obtain additional information on molecular weight and to act as a detector for selection of peaks on which to perform NMR experiments. The sample for analysis was prepared by solid-phase extraction of 5 ml of urine obtained from rats after dosing with 800 mg kg^{-1} of efavirenz, with 0–24 h collection. The extract was dried and reconstituted with 100 μl of 80% D_2O and 20% acetonitrile- d_3 . A 40 μl injection was made onto a 3.9×150 Waters Symmetry C_{18} column. A gradient elution from 80% D_2O and 20% acetonitrile- d_3 to 50% D_2O and 50% acetonitrile- d_3 over 20 min at a flow rate of 0.8 ml min^{-1} was employed for separation. Using a splitter immediately after the column, 95% of the sample went to the UV detector

and onto the NMR spectrometer, whereas 5% went to a Finnigan LC ion-trap mass spectrometer equipped, with an ESI probe operating in the positive-ion mode. The system was plumbed to allow the peak to reach the UV detector and the mass spectrometer at the same time.

The initial experiment, an on-flow ^{19}F detected HPLC-NMR-MS run, takes advantage of the CF_3 group present in the parent drug. Since there are no endogenous fluorinated compounds in rat urine, responses in the spectrum must arise from metabolites of efavirenz. This experiment provided the retention times of the metabolites that were of sufficient concentration to be detected. The ^{19}F chemical shift and the mass of the metabolites were also obtained from this single experiment. **Figure 5** shows the data as a pseudo-2-D plot. The peaks of interest are labeled with their molecular mass.

The next phase of the experimental procedure is to obtain stop-flow ^1H HPLC-NMR spectra at the retention times determined in the on-flow ^{19}F HPLC-NMR experiment. The 1-D and TOCSY spectra

obtained on the minor metabolite with retention time 14.2 min, mass 605 Da, and ^{19}F chemical shift -84.6 ppm are shown in **Figure 6**. The mass-spectral data showed a loss of 80 Da from the parent mass indicative of SO_3 loss. The loss of the methine proton from the cyclopropyl ring, seen clearly from the TOCSY spectrum, and the downfield shift of the remaining methylene protons indicate addition of OH to the cyclopropyl ring. The singlet at δ 6.47 is consistent with reduction in the alkyne. The spin system observed between δ 3 and δ 4 ppm is consistent with cysteinylglycine conjugation. On the basis of these data and the observed molecular mass of 605 Da, this peak is assigned as [7].

The 1-D and TOCSY data obtained on the major metabolite with retention time 20.5 min, mass 507 Da, and ^{19}F chemical shift -83.3 ppm are shown in **Figure 7**. These data clearly show the presence of a glucuronide

Figure 5 Pseudo-2-D plot of on-flow ^{19}F HPLC-NMR-MS data obtained on rat urine after dosing with efavirenz. The data supply the ^{19}F chemical shift, retention time, and mass of the metabolites.

conjugate. The observed changes in the aromatic region of the spectrum are consistent with the 8-*O*-glucuronide conjugate of efavirenz [8].

[8] 8-*O*-glucuronide conjugate of efavirenz

Coeluting with the major metabolite is a component with mass 491 Da and ^{19}F chemical shift -82.1 ppm. Using the mass spectrometer as a detector, the stop-flow was executed when the desired mass, 491 Da, was observed. Although the spectrum (Figure 8) is dominated by the major metabolite, the 8-*O*-glucuronide conjugate of

efavirenz, it is possible to assign several resonances to a glucuronide conjugate. The assignment of this metabolite as the *N*-glucuronide conjugate [9] is consistent with the chemical shift of $\text{H}1'$, δ 4.75, and with the observed molecular mass.

[9] *N*-glucuronide conjugate of efavirenz

Summary

The experiments described serve to illustrate how HPLC-NMR can rapidly provide information on the

structure of drug metabolites. These same methods have been employed in the study of endogenous compounds in biofluids, natural products, polymers, and many other complex mixtures.

The high cost of the HPLC-NMR system is of course a factor that must be taken into consideration. Since most laboratories have seen the value of NMR in its traditional form, it is only necessary to add an HPLC system, an appropriate flow probe, and a flow control unit to an existing spectrometer to enable HPLC-NMR experiments to be performed. The cost of these accessories, or even the cost of a complete system dedicated to HPLC-NMR, is offset by the efficiency of the method. The laborious extraction of minor components from complex mixtures followed by off-line analysis or in the case of synthetic drugs, the synthesis of radiochemically labeled materials with the numerous problems associated with handling and disposing of radiolabeled samples make the cost associated with HPLC-NMR less of a factor.

There are a number of limitations to the utility of HPLC-NMR. The greatest of these is the limitation on the amount of material that can be loaded on the column and consequently moved into the NMR probe. HPLC-NMR is not well suited to the less-sensitive NMR techniques like, which provides critical structural information via long-range interactions. Thus, it is still necessary to isolate minor components from complex mixtures on occasion, and HPLC-NMR should not be viewed as a replacement for conventional NMR. It is a tool that enhances the utility of NMR and like any tool it can be used properly and effectively or misused. Although it has experimental limitations when compared to conventional NMR, many structural problems can be solved using HPLC-NMR without resorting to tedious isolation methods.

The advantages of HPLC-NMR can be summarized as follows:

- Speed of analysis by elimination of the isolation step.
- Ability to obtain structural information and high-quality spectral data from complex matrices.
- The lack of need for perfect chromatographic separation.
- Synergy when directly coupled with MS.

The direct coupling of chromatography, principally HPLC, to NMR spectroscopy continues to be an area of active research and application. Many papers have resulted from a wide range of applications, mainly pharmaceutical studies of degradation and metabolism, and natural product characterization. With the advent of cryogenically cooled probes and higher sensitivity NMR instruments, the field continues to be very active. An up-to-date summary of the current instrumental methodologies applicable can be found in other articles in this encyclopedia via the 'See also' list.

Symbols

R	O...O bond distance
ΔE	internal-energy change
ΔG	free-energy difference
ΔH	enthalpy of bond formation
$\Delta \nu$	O–H stretching frequency

Vibrational spectra are sensitive to intermolecular interactions. This is most clearly evidenced by the differences seen in spectra of condensed phases compared to gases at low pressure which show not just the loss of rotational sidebands but also changes in profile, intensity and position. Hydrogen bonding (H-bonding) provides the most dramatic effects but even the weak van der Waals forces can significantly modify spectra. In liquids, collisions can distort molecular configuration leading to local breakdown of symmetry.

Hydrogen Bonds

Introduction

The hydrogen bond is a weak, fairly directional, interaction represented here as a broken line in the scheme $A-H \cdots B$. Atom A is electronegative, the A–H bond being therefore slightly ionic in character, and atom B possesses an area of basicity such as lone pairs on nitrogen, oxygen and halogen or π electron rings (here B is a group of atoms) in certain aromatic systems. The energies of interaction are of an order of magnitude less than covalent bonds but greater than the very simple non-directional non-covalent forces (van der Waals or dispersion forces) that occur between all molecules. The unit A is generally oxygen, nitrogen or halogen but S–H and in certain circumstances even C–H can engage in H-bonding.

Theoretical and experimental studies suggest that the hydrogen bond is not purely electrostatic but has some covalent character. It is observed from crystallographic and other investigations that the length of the A–H bond increases and the distance between A and B decreases with increasing strength of interaction. In the limit of the weakest H-bonds, A and B are separated by about the

sum of their collision radii. This is slightly greater, by about 0.5 Å than the sum of the van der Waals radii.

Figure 1 shows IR spectra of isopropanol in solution (CCl_4) at various concentrations, the pathlength being adjusted to compensate as nearly as possible for the changes in molarity. It illustrates the dramatic effects of H-bonding (between the hydroxyl groups) on the O–H stretching mode. The free bond yields a relatively narrow band above 3600 cm^{-1} but the singly and doubly H-bonded groups give broad and intense absorptions near 3500 cm^{-1} and 3350 cm^{-1} respectively.

This behaviour of the stretching band $\nu(A-H)$, of shift to lower frequency, increase in overall intensity and band broadening is highly characteristic and indicative of

Figure 1 Effect of H-bonding on the O–H stretching vibration of isopropanol. Reproduced with permission from Colthup NB, Daly LH, and Wiberley SE (1975) *Introduction to Infrared and Raman Spectroscopy*. New York, San Francisco and London: Academic Press.

H-bonding. In extreme cases shifts of more than 2000 cm^{-1} are observed while breadth and intensity increases can be two orders of magnitude or so.

The band shift and intensity changes can be crudely rationalized on the basis of a decrease in force constant due to weakening (lengthening) of A-H and increased polarization on interaction with B.

Raman spectra show similar behaviour to IR in terms of shift and band breadth but the intensity increase is not observed. **Figure 2** illustrates part of the spectrum of a mixture of deuterium chloride and dimethyl ether in the gas phase. The stretching vibration of unassociated DCI can be seen at 2085 cm^{-1} along with rotational side bands, while H-bonded DCI yields a broad absorption underlying the sidebands centred near 1885 cm^{-1} .

The bending vibrations of A-H are affected much less than the stretching vibration. Some broadening and intensification takes place but the small shift is to higher wavenumbers.

The new vibration, $\nu(\text{A-B})$, the overall stretching of the system and one which directly reflects H-bond

strength, is found at low frequencies usually no higher than about 200 cm^{-1} . Probably the strongest H-bonded system in existence, the symmetrical bifluoride ion $(\text{F-H-F})^{-1}$, has $\nu(\text{F-F})$ near 600 cm^{-1} .

Finally, the vibrational modes of bonds directly attached to B are significantly affected. Carbonyl groups which have been extensively studied as H-bond acceptors show downward shifts in $\nu(\text{C=O})$ of as much as 40 cm^{-1} .

Dependence on Temperature and Concentration

In gas and liquid phases the extent of H-bonding decreases with rise in temperature and quantitative band-intensity measurements can give values for various thermodynamic quantities.

In solution similar measurements on concentration dependencies can also provide information on energetics but in addition can be used to allow qualitative conclusions about structure to be made. For instance, **Figure 3** shows the IR spectra of *ortho* and *para* hydroxyacetophenones in solution. The *para* isomer in dilute solution is almost entirely free but the *ortho* isomer by contrast exhibits complete internal H-bonding which, as would be expected, is unaffected by change in concentration.

Correlations with Bond Length

In crystals the stretching vibration is observed to possess a sort of half-parabolic relationship with overall H-bond distance (i.e. length A-B). **Figure 4** shows data from a number of O-H...O systems. Note that data from other families (e.g. N-H...O) fall along separate curves. The sum of the van der Waals radii for two oxygens is about $2.8\text{ \AA}$.

Figure 4 Correlation between the hydrogen-bonded O–H stretching frequency $\nu(\text{O–H})$ and $R_{\text{O}\cdots\text{O}}$ (the O $\cdots$ O bond distance) for O–H $\cdots$ O H-bonds in crystals. The weakly bonded examples are mostly salt hydrates, the strongest examples (those with frequencies below 1000 cm^{-1}) are in the main organic singly-ionized diacid anions (oxygen analogues of bifluoride ion). Reproduced with permission of Springer-Verlag from Novak A (1974) Hydrogen bonding in solids: Correlation of spectroscopic and crystallographic data. *Structure and Bonding* 18: 177–216.

Correlations with Acidity/Basicity and Energy of Interaction

The strength of H-bonding increases with greater proton-donating ability of the A–H moiety and increasing proton-accepting power of the base B. **Figure 5** shows the effect of differing basicity on isopropanol at constant

concentration. Here the solvent itself plays the role of the base. In benzene (inert) the hydroxyl groups are mostly free (the weak sideband indicates a small amount of OH to OH bonding) but are almost entirely H-bonded to either tetrahydrofuran, pyridine or triethylamine. The shift $\Delta\nu(\text{A–H})$ is proportional to solvent $\text{p}K_{\text{a}}$, the values being –2.1, 5.2 and 11 respectively.

Figure 5 Effect of changing the solvent on the O–H stretching vibration of isopropanol. Reproduced with permission from Colthup NB, Daly LH, and Wiberley SE (1975) *Introduction to Infrared and Raman Spectroscopy*. New York, San Francisco and London: Academic Press.

The Badger–Bauer rule states that there is a linear relationship (in solution) between the shift $\Delta\nu(\text{A–H})$ and ΔH , the enthalpy of H-bond formation, but it was formulated originally from early and somewhat limited data. More comprehensive work has since shown that there are deviations from linearity, most obviously in the region of weaker bonding. Each individual system again has a separate relationship, each system here being a one-proton donor (e.g. phenol) with a range of organic bases or vice versa in a particular solvent.

The solvents utilized must of course be inert; CCl_4 or benzene is commonly used. Detailed work suggests that family types must be very exclusive to have a smooth relationship, for example a range of nitrogen bases must be all of the same electronic configuration and must be free of the complications of steric interference.

When a single carbonylic base is used, $\Delta\nu(\text{C=O})$ is found also to yield largely linear relationships with ΔH . Other studies find quite reasonable linear relations between band shift and ΔG (the free energy difference derived from association constants) within specific families of donor and acceptor. While there is some theoretical justification for a linear relationship between shift and enthalpy (or more specifically with ΔE , the internal energy change, in the gas phase) the linear

Figure 6 The IR spectra of (a) $\text{NaH}(\text{CH}_3\text{CO}_2)_2$ and (b) $\text{NaD}-(\text{CH}_3\text{CO}_2)_2$. Reproduced with permission from Hadzi D (1965) *Infrared spectra of strongly hydrogen bonded systems*. *Pure and Applied Chemistry* 11: 435–453.

relation with ΔG is only empirical as the latter cannot be directly related with ΔH (or ΔE).

Estimation of Thermodynamic Quantities

IR absorbance spectroscopy obeys the Beer–Lambert law whereby band absorbance is linearly related to concentration of the molecule in solution. This allows the estimation of the association constant, and thereby ΔG , by measuring the decrease in the intensity of the free A–H band on formation of an H-bond along with knowledge of the total amounts of each substance present. The degree of association (whether dimer, trimer etc.) can be found by examining the way H-bond formation varies with change in concentration. The enthalpy can be estimated by measuring the association constant over a range of temperatures and employing the van't Hoff equation, subject to the usual caveats when using this relationship.

Strong H-Bonds

On the basis of the simple electrostatic picture a much stronger H-bond should result if either A–H or B is ionized. This is indeed found from crystallographic data, the bifluoride ion being a well-known example. Many very short and strongly bonded O–H---O systems exist; **Figures 6(a, b)** shows the IR spectra of sodium hydrogen diacetate, which contains $[\text{CH}_3\text{C}(=\text{O})\text{O}---\text{H}---\text{O}(\text{O}=\text{C})\text{CH}_3]^-$, and its singly deuterated equivalent. The O–O distance is slightly less than 2.45 Å and the proton is located equidistant (or very nearly so) from the two oxygens. It should be noted that the spectra are displayed here in absorbance so that the bands go upwards. Both $\nu(\text{OH})$ and $\nu(\text{OD})$ yield very broad bands starting at around 2500 cm^{-1} and extending to below 500 cm^{-1} . The band maximum is at about 750 cm^{-1} in the first case and somewhere around 600 cm^{-1} in the other. Both spectra display a sharp nick (window) at

about 900 cm^{-1} and such features often abound in spectra of these types of compounds to give very bizarre appearances.

Isotope shifts ($\text{H} \rightarrow \text{D}$) in such compounds are often much lower than normal (which is slightly less than $\sqrt{2}$) though the jagged profiles of the bands can make estimation difficult. All the phenomena suggest that the potential surfaces for vibration are quite anharmonic.

Many medium-strength H-bonds also yield strange features in their stretching bands, carboxylic acids being a case in point.

Explanations for Bandwidth Increase

Surprisingly there is as yet no accepted explanation for the phenomenon of band broadening in H-bonding. It may be that a number of different causes are responsible. A major factor is undoubtedly the abnormality of the vibrational potential functions which appear both from experiment and theory to be often considerably more anharmonic than usual.

Various suggestions for the likely effects of anharmonicity include very short lifetime of the excited vibrational state (uncertainty broadening) and breakdown of the Born–Oppenheimer approximation (i.e. motion of electrons and nuclei are no longer independent, which might be viewed as leading to a multiplicity of potential functions). Special factors may operate in the liquid state; in water the combination of distribution of bond lengths and high polarizability may be connected not only with broad bands but also with the presence of extensive continua that underly the spectrum. In solids, breakdown of selection rules for acoustic modes could contribute to breadth. Widespread interactions with other vibrational modes, including Fermi resonance, are responsible for the strange and broken profiles and can give the appearance of band plurality.

In some instances strong reflection from solids may artificially broaden IR absorbance spectra. This is certainly the case for the bifluoride ion.

Non-Specific Forces in the Liquid State

Compared to the vapour, band shifts similar in sign though smaller in general magnitude to H-bonding, even in its absence, are observed in liquids and solutions. Thus stretching vibrations are slightly shifted to lower wave-number; for instance $\nu(\text{C}=\text{O})$ from PhC(=O)CH_3 is 1709 cm^{-1} in the vapour but 1697 cm^{-1} in hexane and 1692 cm^{-1} in CCl_4 . As a number of different effects are likely to influence the electronic structure and bond dynamics, quantitative predictions are difficult. Attempts to relate shifts to bulk properties only, such as dielectric constant, while ignoring nearest-neighbour interactions have therefore met with little success.

While many of these interactions are essentially very weak they nevertheless can affect vibrational spectra quite significantly. Solute–solvent interactions though only causing minor changes in band profile or position can severely interfere with quantitative analysis. This is because the spectrum of the pure solvent will differ from when it is involved in solution, preventing accurate subtraction if solvent and solute bands overlies each other.

Solute–solvent interactions can occasionally be put to good use, as in the spectral resolution of enantiomeric pairs. By themselves monostereoisomers have identical spectra but when dissolved in an optically active solvent such as D- (or L-)2-octanol (available commercially) yield slightly different spectra. This is because of the asymmetry of the respective interactions which effectively create diastereoisomeric pairs.

Collisional Interactions

Collisions between molecules can cause distortion and alter the symmetry. Carbon disulfide is linear with a centre of symmetry (the two $\text{C}=\text{S}$ bonds are equal in length) and thus the symmetric-stretching vibration at about 650 cm^{-1} is forbidden in the IR. It is however observed as a weak band in IR spectra of liquid CS_2 . Normally forbidden bands can also make appearances when charge-transfer complexes are formed, iodine–pyridine being an example.

Collisions are also responsible for inducing transient polarizations in non-polar molecules which result in a characteristic broad absorbance in the liquid in the range $40\text{--}100\text{ cm}^{-1}$. Both geometric distortion and induced local dipole moments are involved.

Matrix Isolation

It is possible to control and distinguish many interactions by use of the matrix-isolation technique. This involves highly diluting a species of interest with an ‘inert’ and IR-transparent gas, such as argon or nitrogen, and condensing the mixture at very low temperature (liquid helium) onto an IR-transparent window (or a Raman cell). By varying the dilution it is possible to isolate single molecules or controlled associations of molecules in ‘cages’ of the matrix gas. Reactive species can be trapped and studied at leisure. The very low temperature solid phase has the advantage of eliminating translations and collisions yet also yielding generally very sharp bands which can aid in distinguishing mixed species.

Figure 7 shows IR spectra of methanol in various phases including an argon matrix. The bands observed are all from O–H stretching and demonstrate the advantage of the matrix technique. The vapour-phase spectra are dominated by rotational side bands; only H-bonded a multimer can be seen in pure liquid and solid,

though solution shows a dimer as well. Spectra from the matrix at two different dilutions can however distinguish dimer, trimer, tetramer and multimer.

Simple molecular aggregates are amenable to detailed *ab initio* molecular orbital calculations of vibrational modes, which can be compared to experiment to resolve

structural dilemmas. For instance theory predicts that the linear-asymmetric H_2O dimer is more stable than the cyclic-symmetric alternative. Consistent with theory, the low-temperature matrix spectrum can only be fitted to the linear structure.

Inelastic Neutron Scattering

This technique complements IR and Raman spectroscopy in the study of H-bonding in the solid state.

Hyperpolarization

In magnetic resonance, ‘polarization’ means the population difference between the two spin levels for a spin-1/2 nucleus, α and β , which have different energies if the system is exposed to a magnetic field ($E_\alpha < E_\beta$). The magnitude of the energetic transition ΔE depends on the strength of the magnetic field B_0 :

$$\Delta E = E_\beta - E_\alpha = g_n \mu_B B_0$$

Under thermal equilibrium conditions, the population of the levels is ruled by the Boltzmann statistics:

$$\frac{p_\alpha}{p_\beta} = e^{(E_\beta - E_\alpha)/kT}$$

Hence, the ratio of populations (p_α/p_β) depends on the energy difference ΔE and the thermal energy kT . For a typical nuclear magnetic resonance (NMR) magnet (9.6 T, 400 MHz proton frequency), the energy gap ΔE is approximately 1×10^{-25} J, which is very small compared to transitions in the visible (10^{-19} J) and infrared region (10^{-21} J). For the typical NMR magnet at room temperature, the ratio of populations (p_α/p_β) is about $e^{0.0001}$, which is approximately 1. Therefore, in NMR spectroscopy there is only a very small population difference between the two energy levels. This means that the probabilities for an incident photon to be absorbed or to cause stimulated emission are similar. In contrast, in visible absorption spectroscopy virtually all particles are in the electronic ground state and in the infrared absorption spectroscopy approximately 80% of the molecules are in the vibrational ground state; therefore, these optical methods have much better sensitivity. Hence, low

sensitivity is an inherent drawback of NMR methods, leading to a low signal-to-noise ratio and the requirement of high amounts of sample (in the range 10 nmol to 1 μ mol of substance). As a consequence, equilibrium NMR experiments are preferably done on sensitive nuclei (especially ^1H), with high repetition and averaged spectra, at high magnetic fields, with cooled electronics, and sometimes with isotope-enriched samples.

An alternative approach is the introduction of non-Boltzmann nuclear spin states. Such states occur during chemical reactions and upon interaction with electromagnetic radiation. The nuclear spin polarization in addition to the Boltzmann polarization is called 'hyperpolarization.' These transient spin phenomena can be described by irreversible thermodynamics. The spin temperature T_s is defined as

$$T_s = -\frac{h\nu}{k \ln(p_\alpha/p_\beta)}$$

It is also possible that inverted nuclear spin states ($p_\alpha < p_\beta$) are produced, which are thermodynamically described with negative spin temperatures and lead in the spectrum to negative (emissive) signals. Several non-Boltzmann 'hyperpolarization' methods have been developed in NMR. All methods enhance the signal intensity and improve the sensitivity. The most common hyperpolarization NMR methods will be presented in the following section.

Dynamic Nuclear Polarization

Dynamic nuclear polarization (DNP) is a general term for strategies that aim to enhance the thermal nuclear spin polarization using the much higher polarization of unpaired electrons. Several mechanisms have been distinguished based on the molecular motion involved and the properties of the electron spin system.

The Overhauser effect (OE) proposed on theoretical grounds by Albert Overhauser in 1953 and later

experimentally confirmed by Carver and Slichter requires a time-dependent modulation of the hyperfine interaction between unpaired electrons and nuclei on the electron paramagnetic resonance (EPR) timescale (**Scheme 1**). In liquids, the dipolar interaction between electron and nuclear spins (anisotropic hyperfine interaction) is modulated by the rotational and translational motion of the spin-carrying molecules. In metals, the scalar interaction between electrons and the nuclear spin system (isotropic interaction) is modulated by the mobility of the electrons in the conduction band. Cross-relaxation processes due to the modulation of the electron–nuclear hyperfine interaction redistribute the populations of the energy levels during saturation of the electron transitions and lead to an enhancement ε (defined relative to the equilibrium nuclear polarization), given by

$$\varepsilon = 1 - \rho f s \frac{\gamma_e}{\gamma_n}$$

where the coupling factor ρ can take values between -1.0 for a purely scalar interaction and 0.5 for a purely dipolar interaction. The leakage factor f describes the polarization loss of the nuclear spin system due to the presence of the electrons. A value of 0 indicates no relaxation due to the electron–nuclear spin couplings and 1 represents the case of no other nuclear relaxation mechanism than the processes due to the electron–nucleus coupling. The saturation factor s describes how well the electron transitions are saturated by the applied microwave field. For complete saturation $s = 1$. In liquids where the electron–nuclear hyperfine interaction is mainly dipolar, a theoretical maximal enhancement of -330 for ^1H nuclei could be feasible under ideal conditions. For a dominating isotropic hyperfine interaction, a maximal enhancement of 660 is theoretically possible. For an optimal OE the condition $\omega_{0e}\tau < 1$ must be fulfilled (ω_{0e} is the electron Larmor frequency and τ is the correlation time of the paramagnetic species). This condition is difficult to satisfy at high magnetic fields and

Scheme 1 Overhauser effect considering only the isotropic part of the hyperfine interaction: (a) Schematic representation of energy levels and their populations (size of black bars) at thermal equilibrium. $|1\rangle = |\beta_e \alpha_n\rangle$, $|2\rangle = |\beta_e \beta_n\rangle$, $|3\rangle = |\alpha_e \alpha_n\rangle$, $|4\rangle = |\alpha_e \beta_n\rangle$. (b) Irradiation at the electron Larmor frequency ω_{0e} equilibrates the populations of $|1\rangle$ and $|3\rangle$, and of $|2\rangle$ and $|4\rangle$. (c) Cross relaxation with a transition probability W_0 between $|4\rangle$ and $|1\rangle$ enhances the difference between the populations of the energy levels that are connected by the NMR transitions ($|1\rangle \leftrightarrow |2\rangle$ and $|3\rangle \leftrightarrow |4\rangle$). In the case where an anisotropic hyperfine interaction also exists, additional cross relaxation takes place between $|3\rangle$ and $|2\rangle$, resulting in a reverse difference in the population of the energy levels that are connected by the NMR transitions.

Scheme 2 Solid effect: (a) Schematic representation of energy levels and their populations (size of black bars) at thermal equilibrium. There is an admixture of states $|1'\rangle = |1\rangle + q|2\rangle$, $|2'\rangle = |2\rangle - q|1\rangle$, $|3'\rangle = |3\rangle - q|4\rangle$, $|4'\rangle = |4\rangle + q|3\rangle$. For the definition of the state mixing factor q see the main text. (b) Irradiation at frequency $\omega_{0e} + \omega_{0n}$ equilibrates the populations of $|1'\rangle$ and $|4'\rangle$, and therefore enhances the difference in the populations of the energy levels that are connected by the NMR transitions ($|1'\rangle \leftrightarrow |2'\rangle$ and $|3'\rangle \leftrightarrow |4'\rangle$) and leading to a negative enhancement of the NMR signal. (c) Irradiation at frequency $\omega_{0e} - \omega_{0n}$ equilibrates the populations of $|2'\rangle$ and $|3'\rangle$, and therefore generates a reverse difference in the populations of the energy levels that are connected by the NMR transitions and leads to a positive enhancement of the NMR signal.

therefore applications of the OE work more favorably in the low magnetic field regime.

In solids with time-independent hyperfine electron–nuclear interactions, other DNP mechanisms are active. The theoretical maximal enhancement factor is given by the ratio between the electron and nuclear gyromagnetic constant (e.g., ~ 660 for ^1H and ~ 2600 for ^{13}C). The solid effect (SE) has been proposed for electron spin systems with a linewidth much smaller than the Larmor frequency ω_{0n} of the coupled nuclear spins (**Scheme 2**). The mechanism is based on a two-spin process. The nonsecular part of the electron–nuclear dipolar coupling Hamiltonian causes a mixing of nuclear states for the four energy levels. The admixture of states generates a probability proportional to $|q|^2$ for the induction of the otherwise forbidden double and zero quantum transitions by the application of microwave fields with an appropriate frequency. A field with a frequency $(\omega_{0e} + \omega_{0n})$ induces zero quantum transitions and leads to a negative enhancement of the nuclear polarization and a field with a frequency $(\omega_{0e} - \omega_{0n})$ induces double quantum transitions and leads to positive enhancement of the nuclear polarization. q is obtained from first-order perturbation theory and is given by

$$q = -\frac{3}{4} \frac{\gamma_e \gamma_n}{r^3 \omega_{0n}} \sin \theta \cos \theta e^{-i\varphi}$$

where r , θ , and φ are the polar coordinates describing the vector connecting the electron and nuclear spin; r is the distance between the coupled electron and nuclear spin; and γ_e and γ_n are the gyromagnetic constants for the electron and nucleus, respectively.

For coupled electron–nuclear spin systems with electron resonance lines that have a linewidth much broader than ω_{0n} , different mechanisms are responsible for the DNP effect. If the electron resonance line is inhomogeneously broadened by g anisotropy, the dominating polarization transfer mechanism is the cross effect (CE) (**Scheme 3**). The CE is a three-spin process that

involves the interaction between two dipolar-coupled electrons with Larmor frequencies ω_{0e1} and ω_{0e2} that satisfy the relation

$$|\omega_{0e2} - \omega_{0e1}| = \omega_{0n}$$

In particular, this effect was suggested as the dominating mechanism for the large enhancement of the nuclear spin polarization when coupled nitroxide biradicals were used in DNP experiments at a high magnetic field to enhance the NMR signal in magic angle spinning (MAS) NMR experiments.

For strongly dipolar-coupled multiple electrons with a homogeneously broadened linewidth, thermal mixing may dominate the DNP mechanism. Using the concept of spin temperature as a measure of the spin polarization, the mechanism is frequently described in a thermodynamical model in terms of heat flow between several interconnected reservoirs. Off-resonance irradiation of the allowed electron transitions leads to a large polarization gradient across the EPR line, which is equivalent to cooling of the electron dipolar reservoir. If this reservoir is in good thermal contact with the nuclear Zeeman reservoir, the Zeeman reservoir is also cooled in an energy-conserving three-spin (two electrons, one nucleus) exchange process.

A number of strategies based on the use of pulsed microwave fields have been proposed in addition to the previously described continuous wave (CW) techniques. Most of these approaches require high microwave power, which is difficult to provide particularly for very high microwave frequencies. However, recent pioneering work of Griffin has demonstrated the advantages offered by stable high-power-high-frequency gyrotrons for DNP-enhanced MAS NMR experiments at high magnetic fields. In another recent development, it was shown by Golman that the nuclear polarization of ^{13}C -labeled molecules such as $[1-^{13}\text{C}]$ pyruvate in a glassy sample could be enhanced by DNP at low temperature and then brought rapidly in solution by dissolving the sample in a

Scheme 3 Cross effect: (a) Schematic representation of energy levels and their populations (size of black bars) for a coupled system of two electron spins and one nuclear spin at thermal equilibrium. $|1\rangle = |\beta\beta\alpha\rangle$, $|2\rangle = |\beta\beta\beta\rangle$, $|3\rangle = |\beta\alpha\alpha\rangle$, $|4\rangle = |\beta\alpha\beta\rangle$, $|5\rangle = |\alpha\beta\alpha\rangle$, $|6\rangle = |\alpha\beta\beta\rangle$, $|7\rangle = |\alpha\alpha\alpha\rangle$, $|8\rangle = |\alpha\alpha\beta\rangle$. The NMR transitions correspond to $|1\rangle \leftrightarrow |2\rangle$, $|3\rangle \leftrightarrow |4\rangle$, $|5\rangle \leftrightarrow |6\rangle$, $|7\rangle \leftrightarrow |8\rangle$. (b) Irradiation with a frequency ω_{0e1} and the transitions $|1\rangle \leftrightarrow |4\rangle$, $|5\rangle \leftrightarrow |8\rangle$ lead to an enhancement of the population difference between the levels connected by the NMR transitions and to a negative enhancement of the NMR signal. (c) Irradiation with a frequency ω_{0e2} and the transitions $|2\rangle \leftrightarrow |5\rangle$, $|4\rangle \leftrightarrow |7\rangle$ lead to a reverse enhancement of the population difference between the levels connected by the NMR transitions and to a positive enhancement of the NMR signal. Modified from Maly T, Debelouchina GT, Bajaj VS, et al. (2008) Dynamic nuclear polarization at high magnetic fields. *Journal of Chemical Physics* 128: 052211.

hot solvent. The solution containing the hyperpolarized pyruvate was then injected into small model animals and it was possible to show the differences in metabolism between healthy and cancer tissue using directly detected *in vivo* ^{13}C spectroscopic imaging.

Optical Pumping

Absorption of circular polarized radiation can cause nuclear polarization. For the investigation of this phenomenon, Kastler was awarded the Nobel Prize in Physics in 1966.

To optically pump a spin species, an electronic transition is needed. The mechanism can be understood straightforwardly in alkali metal atoms, having a single s electron that is excited upon absorption. Since according to the selection rules for electronic dipole transitions, absorption changes both the principal quantum number n and the orbital momentum quantum number l . Therefore, from a $2s^1$ state, the $3p^1$ state can be produced but not the $3s^1$ state. This is due to the conservation of the total angular momentum since a photon is a boson with a spin of 1. In addition, the photon has a helicity of $+1$ (left circular polarized) or -1 (right circular polarized) that changes the magnetic quantum number m_l selectively by either $+1$ or -1 . Hence, in our example, from the three $3s$ states selectively only a single one can be populated. If the spin system is exposed to a magnetic field, magnetic electron polarization is produced.

The polarization can be transferred to other spin systems. The electron polarized alkali metal atom, for example, can form a van der Waals complex with noble

gases in which Fermi contact interaction allows spin exchange from the electron to the nuclei of the noble gases. Polarized ^{129}Xe gas has been applied for many NMR studies of solids, thin films, and surfaces as well as in MRI, for example, for imaging of human lungs. Also, polarization transfer to biologically relevant nuclei such as ^{31}P is possible.

In inorganic semiconductors, near-infrared laser excitation of unpolarized valence-band electrons produces spin-polarized electron-hole pairs that polarize nuclear spins to which they are coupled.

Optical Nuclear Polarization

In 1967, Maier and Wolf observed nuclear hyperpolarization in pure anthracene single crystals upon illumination with unpolarized white light. Later the effect was also found in doped crystals of other condensed aromatic compounds. The effect has a maximum at rather low fields (around 0.01 T), although it often remains observable at higher fields. Mostly samples are polarized outside the magnet and, due to long T_1 , transferred conveniently into the magnet for the NMR measurement. It has been shown that the origin of the optical nuclear polarization (ONP) is electron hyperpolarization, called optical electron polarization (OEP), occurring in the triplet state.

Upon light excitation, excited electronic singlet states are populated (Scheme 4). Intersystem crossing (ISC) allows for population of electronic triplet states. Owing to zero field splitting (ZFS), in molecules the three triplet electron states are not degenerate. As pointed out by

Scheme 4 Formation of electronic triplet states from the excited singlet states. Although in spherical atoms all three triplet states are degenerate, in molecules having lower symmetry the three triplet levels (T_x , T_y , and T_z) occur at different energies even at zero magnet field (ZFS). Since ISC based on spin-orbit coupling is highly spin selective, the three triplet states may not be populated according to the Boltzmann distribution.

Wolf and van der Waals in the late 1960s, spin-orbit coupling pathways allowing for ISC are highly spin selective. Therefore, often only one of these three electronic triplet states is populated – the one that has the symmetry matching the preceding excited singlet state. Similarly, the decay to the ground state S_0 is controlled by spin-selective ISC. Hence, non-Boltzmann electron population and therefore electron hyperpolarization is created. This electron hyperpolarization can be transferred to nuclear hyperpolarization by static hyperfine coupling during the lifetime of the triplet state. As shown by both Veeman and Stehlik, the optimum polarization transfer to nuclei can be reached if a selective mixing of the electronic triplet states by a hyperfine interaction occurs, which leads to level anticrossing (LAC) by conserving the total magnetic quantum number. In molecular crystals, migration of triplet excitations and their trapping may control the kinetics and site of the occurrence of ONP.

Chemically Induced Dynamic Nuclear Polarization in Liquid State

Chemically induced dynamic nuclear polarization (CIDNP) was first reported to occur in NMR experiments on dark organic radical reactions by Bargon and Fischer as well as by Ward and Lawler in 1967. Soon, CIDNP was also observed in a photochemical reaction. The term ‘photochemically induced dynamic nuclear polarization (photo-CIDNP)’ refers to this specific photochemical origin of the phenomenon. CIDNP has been explained by the radical pair mechanism (RPM)

Scheme 5 The RPM as occurring in a solution of a flavin dye (F) and an aromatic amino acid (A) triggered by light. The reaction path depends on the electron spin state of the radical pair (S or T_0). The electron spin state is influenced by nuclear spin states via hyperfine (hf) interactions.

that was introduced independently by Closs and Closs as well as by Kaptein and Oosterhoff in 1969. This mechanism is caused by different nuclear spin sorting leading to a different chemical fate of the products. Owing to coherent S - T_0 mixing, upon ISC the spin state of the radical pair oscillates between a singlet (S) and a triplet (T_0) state. The radicals forming a singlet radical pair may recombine, whereas the triplet products are forced to diffuse apart. Hence, this mechanism requires mobility and can build up CIDNP only in a fluid phase. Later, the mechanism was extended to S - T_+ and S - T_- mixing as well, for example, occurring in biradicals and at low fields. In addition, an electron–nuclear Overhauser cross-relaxation mechanism operating in the liquid state has also been observed, which also explains cyclic reactions. In a triplet Overhauser mechanism, nuclear polarization is created upon ISC from an excited singlet state to a triplet state. Although the RPM is based on fast coherent evolution of an electron–electron–nuclear spin system and spin state sorting in alternative reaction pathways, the Overhauser mechanism relies on usually slower incoherent cross relaxation that transfers polarization from electrons to nuclei. The latter mechanism requires a

Scheme 6 The g -values of two radicals $R_1^\bullet$ and $R_2^\bullet$ of different chemical constitution may differ. In radical $R_1^\bullet$, interaction with nuclei leads to hyperfine (hf) splitting with the hf-constant a . Since the nucleus (e.g., a proton, H) can be in two different nuclear spin states ($+1/2$ or $-1/2$), in a magnetic field $R_1^\bullet\text{H}$ has two different Zeeman frequencies. Hence, the $[R_1^\bullet\text{H}-R_2^\bullet]$ radical pairs evolve with two different ISC frequencies.

matching of the cross-relaxation time to the lifetime of the radical pair, whereas transient polarization from the RPM cancels under steady-state conditions for cyclic reactions.

Typical systems for liquid photo-CIDNP experiments acting according to the RPM are aromatic amino acids (A) together with organic dyes such as flavins (F) (Scheme 5). Under illumination, the flavin undergoes transformation to the triplet state, which is a strong electrophile, and this removes an electron from the aromatic amino acid. For a short time, a correlated radical pair occurs in which the spin evolution is driven by interactions by the nuclei (hyperfine coupling constant a) or by the differences in the g -value between both radicals (Scheme 6). These interactions can lead to different Larmor frequencies of both radicals and therefore to oscillations of between singlet (S) and triplet (T_0) states of the correlated radical pair. Recombination of the radicals is only allowed in the singlet radical pair, whereas it is forbidden in the triplet radical pair that will diffuse apart. Hence, nuclear spin selection leads to different chemical products. If the recombination product has chemical shifts different to those of the escape product, photo-CIDNP signals can be detected.

Liquid photo-CIDNP NMR has been applied extensively to explore surfaces of proteins in solution. In particular, the occurrence of aromatic amino acids has been exploited. The CIDNP polarization can be transferred from one species to another either by dipolar cross

relaxation or via spin-spin coupling. The occurrence of CIDNP has also been used for the interpretation of reaction mechanisms of organic reactions in liquid phase.

Photochemically Induced Dynamic Nuclear Polarization in Solid State

In the solid state, photo-CIDNP was observed for the first time in quinone-blocked frozen bacterial reaction centers (RCs) of *Rhodobacter (Rb.) sphaeroides* R26 under continuous illumination with white light at 9.4 T by Zysmilich and McDermott in 1994. In the meanwhile, the Matysik group had observed the solid-state photo-CIDNP effect also in many other natural photosynthetic RCs, including those of plants. Therefore, the effect appears to be an intrinsic property of natural RCs and its origin may be linked to high efficiency of electron transfer in natural photosynthesis. The solid-state photo-CIDNP effect has been observed with ^{13}C and ^{15}N NMR, whereas, despite various attempts, ^1H observation has not yet been successful. For ^{13}C NMR, an enhancement factor of more than 10 000 has been observed at 4.7 T. Such enhancement allows for observation of photo-CIDNP signals directly in cells without further purification.

Upon photochemical excitation of the primary electron donor P, which is the so-called 'special pair' in bacterial RCs from *Rb. sphaeroides*, an electron is transferred to the primary acceptor, a bacteriopheophytin (BPhe) molecule Φ (Scheme 7). The radical pair ($\text{P}^{+\bullet}\Phi^{-\bullet}$) is initially in a pure singlet state and therefore highly electron polarized. This electron polarization can be observed with EPR spectroscopy as chemically induced dynamic electron polarization (CIDEP). In quinone-reduced or quinone-depleted RCs, further electron transfer is blocked. Therefore, the singlet radical pair can either relax to the electronic ground state or, depending on the strength of the applied magnetic field, be transferred to a triplet radical pair. During ISC, electron polarization is transferred to nuclei by the three-spin mixing (TSM) mechanism. In the differential decay (DD) mechanism, net photo-CIDNP is produced by different contributions of the two spin states of the spin-correlated radical pair to the spin evolution. The triplet radical pair recombines to a donor triplet ^3P and an acceptor singlet. In RCs having a long lifetime of the donor triplet, ^3P , as in R26, the differential relaxation (DR) mechanism occurs by incomplete cancellation of nuclear polarization of both branches. Hence, the solid-state photo-CIDNP effect may be produced by up to three mechanisms running in parallel and possibly with opposite sign. In time-resolved experiments, using flash lasers for excitation, transient photo-CIDNP, due to the different decay times of both states of the radical pair, may occur.

Scheme 7 The three mechanisms producing the solid-state photo-CIDNP effect, called three-spin mixing (TSM), differential decay (DD), and differential relaxation (DR).

The solid-state photo-CIDNP effect is currently mainly used to explore the photochemical machineries of various photosynthetic RCs. Of particular interest are the special pair of purple bacterial RCs and the donor of photosystem II.

Para-Hydrogen-Induced Polarization

In 1986, Weitekamp and Bowers proposed, using theoretical arguments, the effect of *para*-hydrogen-induced polarization. The phenomenon is explained by the quantum mechanical properties of homonuclear diatomic molecules. From symmetry requirements the total wave function for diatomic hydrogen must be antisymmetric with respect to exchange of the two (indistinguishable) protons. Since in the relevant temperature regime transitions take place only between rotational and nuclear spin states, it follows that the symmetric nuclear spin states are correlated to antisymmetric rotational states with odd rotational quantum numbers (*ortho*-hydrogen), and that the antisymmetric nuclear state is correlated to symmetric rotational states with even rotational quantum numbers (*para*-hydrogen). The antisymmetric singlet

state of the nuclear spins is given by

$$|\psi\rangle_{para} = \frac{1}{\sqrt{2}}(|\alpha\beta\rangle - |\beta\alpha\rangle)$$

and the three symmetric triplet states are given by

$$|\psi_1\rangle_{ortho} = |\alpha\alpha\rangle, \quad |\psi_2\rangle_{ortho} = |\beta\beta\rangle, \\ |\psi_3\rangle_{ortho} = \frac{1}{\sqrt{2}}(|\alpha\beta\rangle + |\beta\alpha\rangle)$$

If the two ^1H nuclei from *para*-hydrogen are transferred pairwise in a catalyst-controlled hydrogenation reaction onto suitable target molecules that have triple or double bonds, the symmetry is broken and the two ^1H nuclei become distinguishable. The generated spin order of the product molecule can be converted into an NMR detectable signal by excitation with an appropriate pulse ($\pi/4$ pulse). In principle, since it is relatively simple to obtain highly enriched *para*-hydrogen by passing hydrogen gas over a paramagnetic catalyst such as charcoal at cryogenic temperature, the strategy makes it possible to generate highly polarized nuclear spin systems. The technique has found its main application in inorganic chemistry where it was used to study the intermediate

steps and end products of organometallic catalytic reactions. However, recent attempts have shown that it may be possible to generate hyperpolarized molecules with biological relevance using the *para*-hydrogen strategy. In particular, it was demonstrated by Golman's group that the high polarization of the ^1H spin system of molecules after hydrogenation could be transferred to heteronuclei with much longer lifetimes, thus making possible biomedical applications in which hyperpolarized ^{13}C nuclei are detected *in vivo*. Furthermore, an interesting phenomenon related to the lifetime of the singlet nuclear spin state was published recently by the group of Levitt. It was shown for molecules with high symmetries that this state could have a substantially longer lifetime than the usual spin-lattice relaxation rate constants in NMR.

Introduction

It is now more than 14 years since the first images of mouse lungs with hyperpolarized (HP) ^{129}Xe gas were published and 12 years since the first images of human lungs with HP ^3He gas were demonstrated. Since that time, gas polarization techniques and MRI methodology have developed such that HP gas MRI is now providing images of various functional aspects of lung physiology in a wide range of lung diseases.

Several comprehensive reviews have been written to date on both the physics of gas polarization and non-clinical applications of HP gas NMR and the growing number of applications in biomedical science and clinical radiology. This article focuses on biomedical applications and human lung imaging in particular, while references about applications in other fields are given in the Further Reading section. It is fair to say that ^3He has made more impact to date than ^{129}Xe in human lung imaging, with numerous clinical research examinations having been performed at over 10 sites worldwide using whole-body MRI scanners in a wide range of chest diseases, including asthma, cystic fibrosis, emphysema, and lung cancer. However, developments in ^{129}Xe polarization levels have

facilitated high-quality ^{129}Xe images in humans in recent years, which in combination with its higher abundance is likely to make ^{129}Xe more attractive in the future.

Properties of ^3He and ^{129}Xe

^3He is a monatomic radiostable isotope of the inert noble gas helium. It has a very low natural abundance on earth of 0.000 137%, with most of the ^3He derived from tritium in the nuclear industry. From an NMR perspective, the spin 1/2 of the ^3He nucleus coupled with its relatively high gyromagnetic ratio ($\gamma_{^3\text{He}} = 32.3 \text{ MHz T}^{-1}$) makes it very sensitive to NMR techniques. ^3He is a highly diffusive gas due to its low atomic weight, having a self-diffusion coefficient of $2.0 \text{ cm}^2 \text{ s}^{-1}$, which is reduced to around $0.9 \text{ cm}^2 \text{ s}^{-1}$ in air.

^{129}Xe is a naturally occurring isotope of the heavy noble gas xenon. Its natural abundance is relatively high at 26.44%. It is NMR active with a nuclear spin of 1/2, and its gyromagnetic ratio is lower than that of ^3He ($\gamma_{^{129}\text{Xe}} = 11.9 \text{ MHz T}^{-1}$), which results in a lower sensitivity to NMR detection. ^{129}Xe is less diffusive than ^3He with a self-diffusion coefficient of $0.06 \text{ cm}^2 \text{ s}^{-1}$ and a diffusion coefficient of $0.14 \text{ cm}^2 \text{ s}^{-1}$ in air. Xenon is not completely inert due to its large electronic shell, and has anesthetic properties. A concentration of 71% leads to general anesthesia in 50% of patients, and from a safety perspective, patient monitoring is required for *in vivo* NMR with xenon.

The NMR T_1 relaxation times of ^3He and ^{129}Xe are potentially very long and can approach the dipole-dipole limit of days, provided the gas is stored in a magnetically homogeneous environment. Both ^3He and ^{129}Xe can be imaged in the gaseous state using conventional Boltzmann thermal polarization via the Zeeman effect. However, the low spin density of the gaseous state makes the signal too weak for *in vivo* MRI, which necessitates the use of hyperpolarization techniques.

Gas Polarization with Optical Pumping

In a conventional NMR experiment, the nuclear polarization depends on the static magnetic field $\mathbf{B}_0$, and is typically on the order of $\sim 10^{-5}$ for static fields of several Tesla. Hyperpolarization techniques allow this value to be raised by 5 orders of magnitude, resulting in nuclear polarizations exceeding 10%. For noble gases, hyperpolarization can be achieved by optical pumping techniques. These rely on transfer of angular momentum from

Figure 1 Schematic of a typical SEOP setup. A circularly polarized laser is incident on a glass cell containing the polarizing gas mixture. Here, the mixture for ${}^3\text{He}$ is shown, containing mainly ${}^3\text{He}$ with a small added quantity of N_2 . The cell is placed inside an oven to evaporate the Rb present inside. B_0 coils provide a magnetic field to lift the spin degeneracy, and connections to a manifold allow gas handling.

circularly polarized light to the nuclear spin via the electron spin as an intermediate stage. In spin-exchange optical pumping (SEOP), photon angular momentum is first transferred to electrons of an alkali metal (typically Rb). This creates a very high electron spin polarization (often up to 99%), which is transferred to the noble gas nucleus by spin exchange during collisions between the noble gas and the highly polarized alkali metal.

A typical setup for SEOP is shown in **Figure 1**. A circularly polarized laser resonant with a Rb absorption line at $\lambda = 795 \text{ nm}$ is incident on a glass cell containing the polarizing gas mixture. The cell is placed inside an oven, in order for the Rb to be present in the gas phase. A set of coils creates a weak B_0 field ($B_0 \sim 1 \text{ mT}$) to remove the degeneracy of the spin states and enable optical pumping. The cell is part of a gas manifold to allow extraction of polarized gas and subsequent refilling.

Figure 2 shows how absorption of a polarized photon leads to electronic spin polarization at the alkali metal. Light with circular polarization σ^+ excites electrons from the $\downarrow$ spin state of the ground-state orbital to the $\uparrow'$ spin level of the excited orbital, according to the selection rule $\Delta m = +1$. The populations of excited states $\uparrow'$ and $\downarrow'$ become mixed via collisions, and their populations are rapidly equalized. The presence of N_2 quenches radiative decay and enables nonradiative transitions with $\Delta m = 0$. Thus, absorption of a σ^+ photon, collisional mixing of $\uparrow'$ and $\downarrow'$, and nonradiative decay lead to a net transfer from $\downarrow$ to $\uparrow$ with an ideal efficiency of 50%. This electron spin polarization is then transferred to the noble gas spin via the Fermi contact interaction during collisions.

This transfer is more efficient for ${}^{129}\text{Xe}$ than for ${}^3\text{He}$, which means that in a sealed cell ${}^{129}\text{Xe}$ reaches its maximum polarization within a couple of minutes, while

Figure 2 Absorption of a circularly polarized photon in presence of a static magnetic field leads to preferential excitation into one of the excited spin states. Populations of the excited spin states are rapidly equalized, and nonradiative decay in the presence of N_2 leads to a net electron transfer from one spin state into the other.

for ${}^3\text{He}$ the process takes typically 24 h. Surface relaxation on the cell walls is the dominating source of polarization loss, and the limiting factor for maximum polarization attainable. SEOP of ${}^{129}\text{Xe}$ has to be performed at low partial ${}^{129}\text{Xe}$ pressures, while the partial pressure of ${}^3\text{He}$ can be kept high. For this reason, ${}^{129}\text{Xe}$ has to be accumulated after polarization, typically by freezing it out in liquid N_2 . Early commercial SEOP polarizer prototypes yielded liter quantities of gas polarized to approximately 30% for ${}^3\text{He}$ and 10% for ${}^{129}\text{Xe}$. Recent advances in laser and polarizer technology

allowed the construction of a commercial prototype ^{129}Xe polarizer yielding 10 l of gas per hour polarized to over 50%.

For polarizing ^3He , metastable exchange optical pumping (MEOP) is an alternative to SEOP. In MEOP, electron spin polarization is created directly in the noble gas, when the ^3He atoms are excited to the metastable 2^3S_1 state by a radio-frequency (RF) discharge. The lifetime of this state is long enough to become the ground state of an optical pumping process similar to that used in SEOP, except that here the pumping and the transfer from electronic to nuclear polarization takes place directly at a ^3He metastable molecule without the intermediate alkali stage. MEOP is a relatively fast process compared to SEOP, and polarizations of 70% can be reached within a couple of seconds, but the technique works only at low pressures, and in order to obtain useful quantities for MRI the gas has to be pressurized without losing polarization.

MRI Implementation

B_0 Field Strength

The polarization of HP gases is independent of the B_0 of the MRI magnet, and as such there is scope for imaging at lower field strengths. Low-field imaging of HP gas represents a cheap solution and allows the possibility of probing the physiological effects of posture with magnets oriented in an upright position. However, the larger commercial MRI vendors are pushing their multinuclear imaging efforts on to higher field systems (1.5 T and above) and preliminary results at 3 T are not discouraging. Some theoretical discussion has taken place as to the optimum theoretical field strength for HP gas imaging. The answer is dependent on the size of the object, which dictates the coupling to noise from the sample. Although interesting from a technical and theoretical point of view, this optimum B_0 has yet to be proven experimentally. From a practical perspective, high-quality ^3He images are routinely acquired on modified clinical 1.5 T scanners.

Radio-Frequency Hardware

Transceiver coils for HP gas MRI need to be large enough to cover the adult lungs and airways (approximately $30 \times 30 \times 18 \text{ cm}^3$) without subject discomfort. Furthermore, the coils must be able to function safely and efficiently, often within the confines of a clinical whole-body scanner that has limited bore access. Most whole-body systems are fitted with integrated proton body transmit coils and therefore resonant coupling between this volume resonator and the HP volume coil needs to be considered in the design process. Other

design constraints include portability and minimization of scanner down time due to hardware changes between ^1H and HP nuclear imaging examinations. From an application perspective, HP gas MRI is very sensitive to flip angle by virtue of the nonrenewable polarization. Thus, the transmit coil should provide a uniform excitation angle across the whole of the lungs for a range of flip angles. A large-volume resonator such as an insert birdcage provides a solution to many of these requirements, although higher receiver sensitivity may be attained with a closer fitting coil or coil array, the latter of which also allows parallel imaging.

Pulse Sequence Considerations

HP gases are by definition in a nonequilibrium state, with their large magnetization decaying towards thermal equilibrium at the longitudinal relaxation rate T_1^{-1} . For ^3He the decay of hyperpolarization is dominated by wall relaxation in the absence of paramagnetic gases such as O_2 . The longitudinal relaxation time T_1 can range from several days in specially designed storage vessels to approximately 20 min in plastic bags often used for delivery of the gas to the patient in a clinical environment. However, in the presence of O_2 diffusion across the magnetic field associated with this paramagnetic substance becomes the dominating relaxation process. In ^3He human lung imaging, the presence of intrapulmonary O_2 leads to an *in vivo* T_1 of approximately 20 s.

Although these T_1 values sound very long compared to typical ^1H relaxation times, one must not forget that in the case of HP media T_1 relaxation does not lead to recovery of magnetization, but to loss. In other words, HP magnetization is nonrecoverable during an MRI experiment, and each RF pulse destroys a fraction of the available signal. Hence, MRI pulse sequences for HP species should be fast (because of the steadily decaying magnetization) and efficient, that is, use as few RF pulses as possible (because of the nonrecoverability of hyperpolarization).

The main workhorse of HP noble gas imaging is the spoiled gradient echo (SPGR) sequence, also known as fast low-angle shot (FLASH) (see **Figure 3a**). After acquisition of the gradient echo the remaining transverse magnetization is spoiled by strong gradients on one or several axes. In ^1H imaging this sequence leads to a steady state due to T_1 recovery between pulses. For the reasons mentioned above, this is not the case for HP media. The transverse magnetization after the n th RF pulse follows the following equation:

$$M_n = \sin(\alpha) \cos^{n-1}(\alpha) e^{-\text{TR}(n-1)/T_1} M_0$$

where M_0 is the initial magnetization, TR is the sequence repetition time and α is the constant flip angle used in the

Figure 3 2D pulse sequences commonly used for imaging HP gases. (a) SPGR sequence, where magnetization is spoiled by gradients after each phase encode view. (b) SSFP sequence, in which balancing of gradients leads to recycling of hyperpolarization.

sequence. The depletion of magnetization during the sequence leads to a weighting imposed on the acquired k -space data. In a 2D experiment, k -space lines that are acquired earlier have a higher weight than later ones.

This k -space filter generally leads to blurring of the resulting image. It also has important consequences for the phase encoding strategy used. Centric phase encoding that acquires the center of k -space first yields a higher signal-to-noise ratio (SNR), as the total image intensity is determined by the amplitude of the k -space center. Sequential encoding, passing through k -space from one edge to the other, on the other hand, gives a better effective resolution, as features of high spatial frequencies are emphasized.

A method to correct for the k -space filtering effect is the use of SPGR with variable flip angle. Instead of using a constant flip angle throughout, it is varied according to

$$\alpha(n) = \tan^{-1} \frac{1}{\sqrt{N-n}}$$

where N is the total number of RF pulses or phase encodes and n is the current pulse number. The flip angle

is increased gradually, keeping the transverse magnetization after each pulse constant, until all magnetization is used up in the last pulse, which has a flip angle of 90° .

Alternatively to SPGR, balanced steady-state free precession (SSFP) sequences, also known as TrueFISP or FIESTA, can be used for imaging HP gases. The timing diagram of a 2D SSFP sequence is shown in **Figure 3(b)**. Instead of spoiling transverse magnetization, it is re-focused by balanced gradients whose integral vanishes after one TR. A startup RF pulse of flip angle $\alpha/2$ is applied before the first-phase encode step, and RF pulses are phase cycled by 180° from pulse to pulse, effectively flipping the magnetization vector back and forth around a transverse axis.

Because SSFP sequences recycle available magnetization by refocused gradients, they enable the use of higher flip angles, thus yielding images of higher SNR than SPGR. Alternatively, when using lower flip angles, recycling leads to a flatter k -space filter, reducing blurring similar to SPGR with variable flip angle. A drawback of balanced sequences is the appearance of characteristic banding artifacts well known from ^1H SSFP images. In ^3He lung imaging it has been demonstrated that these can be effectively eliminated by using very short echo times.

The high diffusivity of ^3He and, to a lesser extent, ^{129}Xe can pose a further imaging constraint unique to HP gas MRI, because the imaging gradients act to dephase the transverse magnetization. The diffusion-related signal loss is quantified by the signal attenuation at the center of the readout echo by the factor $\exp(-b(\tau)D)$, where D is the diffusion coefficient of the gas and the b value for any gradient waveform $G(t)$ applied to a nucleus with gyromagnetic ratio γ is defined by

$$b(\tau) = \int_0^\tau |k(t)|^2 dt \quad \text{with} \quad k(t) = \gamma \int_0^t G(t') dt'$$

Short echo time asymmetric readout gradients provide a robust solution to minimizing this diffusional signal loss.

Imaging Methods

Ventilation Images

The basic imaging sequences outlined in the previous section are typically used to obtain static ^3He ventilation images, acquired while the patient holds his or her breath. In these images pixel intensity correlates with ^3He spin density. **Figure 4** shows representative ventilation images from a healthy volunteer and a cystic fibrosis patient. The difference between healthy and diseased lungs is apparent in a considerably more heterogeneous signal

Figure 4 Representative ^3He ventilation images from (a) a healthy volunteer and (b) a cystic fibrosis patient. While the lungs are homogeneously ventilated in the healthy person, airway obstruction in cystic fibrosis leads to the typical patchy ventilation.

distribution in the latter. Regions of low or no signal within the lung are known as ventilation defects, and their size and number is a marker correlating with the severity of obstructive and restrictive lung diseases.

Diffusivity Maps

One of the great promises of HP noble gas MRI in lungs is the fact that it can be sensitized to length scales much smaller than the actual pixel size, making it possible to probe the alveolar structure. Restrictive diseases such as emphysema begin by degeneration and widening of the alveoli, which have a typical diameter of $400\ \mu\text{m}$ upon inhalation in a healthy person. This diameter can expand dramatically due to disease, thus reducing the alveolar surface area necessary for gas exchange with the vascular system. Changes on this length scale can be detected by diffusion sensitized HP noble gas MRI, which thus allows early diagnosis of these diseases.

Diffusion sensitization is accomplished by introducing a bipolar gradient after the slice selection gradient and before the phase and frequency encoding gradients. Because the time integral of this diffusion gradient is zero, static spins experience no net dephasing, whereas spins diffusing through the magnetic field gradient experience some net dephasing and loss in coherence of the transverse magnetization. The simplest and most common model to describe this dephasing is monoexponential:

$$S_1 = S_0 \exp(-b \cdot \text{ADC})$$

where ADC is the apparent diffusion coefficient and b is the diffusion dephasing parameter as defined earlier. The mono-exponential model assumes Gaussian diffusion, which is not a good assumption for all regimes of gradient strength, diffusion coefficient and length scale under investigation. Currently much research is being conducted on non-Gaussian diffusion in this context.

The ADC value is sensitive to the environment of the probed nuclei. In the absence of any boundaries or walls, it is equal to the free diffusion coefficient in air, D_0 . However, if the gas diffuses in a restricted environment, where atoms are likely to collide with a wall within the duration of the diffusion gradient, the ADC will be smaller than the D_0 . Consequently, the ADC can be regarded as a measure of the geometric properties of the environment the gas diffuses in, with a lower ADC corresponding to a more restricted environment.

If the time difference between the onsets of the positive and negative lobe of the bipolar gradient is designated by Δ , and the diffusion coefficient of the noble gas in air is D_0 , the length scale l probed by an ADC measurement is given by

$$l = \sqrt{2D_0\Delta}$$

The free diffusion coefficients in air are approximately $D_0 = 0.9\ \text{cm}^2\ \text{s}^{-1}$ for ^3He and $D_0 = 0.06\ \text{cm}^2\ \text{s}^{-1}$ for ^{129}Xe . Owing to this difference, the two gases are sensitive to different length scales within the lung for the same sequence timing.

At present, most patient studies have been undertaken using ^3He . Commonly, a dual-interleaved 2D SPGR sequence is used, with one interleave being a normal SPGR imaging sequence (also called the $b=0$ case), and the other containing the diffusion gradient with a b -value of around $b = 1.5\ \text{s}\ \text{cm}^{-2}$. With $\Delta = 1\ \text{ms}$ this leads to a probed length scale of approximately $0.4\ \text{mm}$, which is the typical size of the alveoli.

Interleaving the sequence allows spatial registration of images from both interleaves. The ADC can then be calculated pixel-by-pixel according to the mono-exponential model from the signal decay between the first and second interleave. Examples of ADC maps

Figure 5 ^3He ADC maps (a and c) and histograms (b and d) from a healthy person and an emphysema patient. Emphysema results in widened alveoli, which leads to regions of elevated ADC. This can be seen from the brighter colors in (c). In the case presented here the patient also suffers from obstruction, apparent from the patchy ventilation. From the histograms it can be inferred that the average ADC is also higher in lungs with emphysema.

and histograms obtained with ^3He in healthy and diseased volunteers are shown in **Figure 5**. Patients with emphysema have regionally elevated ADC values, which is indicative of alveolar degeneration. For healthy persons the average ^3He ADC is typically on the order of $0.2 \text{ cm}^2 \text{ s}^{-1}$, while it is higher for emphysema patients.

Intrapulmonary pO_2

The dependence of T_1 on the presence of paramagnetic O_2 can be used to sensitize HP noble gas MRI to the intrapulmonary partial oxygen pressure pO_2 . For ^3He at body temperature, it has been shown that T_1 depends on pO_2 via

$$T_1 = \frac{\xi}{\text{pO}_2}$$

where $\xi = 2.61 \text{ bar}$ is an empirical constant. As mentioned previously, for physiological values of pO_2 and in the absence of RF pulses, this relaxation mechanism is the dominant cause of polarization loss. As intrapulmonary O_2 is continually exchanged with CO_2 from

the bloodstream, pO_2 itself is not constant during a breath hold. Its time course is often empirically modeled by a linear decrease according to

$$\text{pO}_2(t) = \text{pO}_2(0) - Rt$$

Although this is a valid approximation for short breath holds in humans, an exponential decay formula is a better model for long breath holds or in species with a faster metabolism (e.g., mice):

$$\text{pO}_2(t) = \text{pO}_2(0) \exp\left(-\frac{t}{\tau}\right)$$

Regional quantification of intrapulmonary pO_2 is possible by acquiring the same slice in a time series, and fitting its pixel intensities to the empirical decay formula. The challenge lies in separating the effect of RF depolarization from T_1 decay. This can be done either using a double acquisition approach where either the RF flip angle or the delay between images is varied, or by first acquiring two images in rapid succession to estimate the local flip angle, and then imaging at a fixed delay to monitor T_1 decay.

Figure 6 A dynamic series of ^3He images, acquired during inhalation. To achieve the necessary temporal resolution, a radial k -space trajectory was used.

Although these methods are capable of obtaining physiologically meaningful values of both initial oxygen partial pressure p_0 and linear decay rate R , to date relatively few studies have been conducted investigating the measurement of intrapulmonary $p\text{O}_2$ compared to static ventilation imaging or ADC measurement.

Dynamic Imaging

HP gas MRI is not constrained by saturation recovery of the signal, which enables very rapid imaging with short repetition time to capture gas flow dynamics and time-resolved processes such as air trapping. Rapid time-resolved 2D sequences (e.g., with radial k -space trajectories) are effective, as they oversample the center of k -space and can be readily adapted to sliding window reconstruction. By modulating the flip angle used with respect to the rate of inhalation, the images can be weighted according to gas flow rate in order to delineate the major airways where gas flux is higher. A representative time series of ^3He images acquired during inhalation with a 2D radial sequence is shown in **Figure 6**.

^{129}Xe Exchange Methods

Compared to ^3He , ^{129}Xe is inherently more difficult to detect by NMR. Its gyromagnetic ratio is about three

Figure 7 ^{129}Xe dynamic spectra acquired *in vivo*, the large ^{129}Xe chemical shift allows differentiation of the different compartments: 0 ppm in the airspaces, 197 ppm in the lung tissue barrier, and 211 ppm in the red blood cells. Reproduced from Driehuys B (2006) *Proceedings of the National Academy of Sciences* 103(48): 18278–18283, with permission from PNAS.

times lower, and its lower Larmor frequency directly translates into a three times lower signal. Nevertheless, in addition to its lower price, ^{129}Xe has another significant advantage over ^3He : it is soluble in blood, with a large chemical shift of approximately 200 ppm between the gas and the dissolved phase (**Figure 7**).

This solubility can be exploited to probe gas exchange between the airspaces and the vascular system, both in spectroscopic and imaging MR experiments. On the other hand, the solubility of ^{129}Xe also results in anesthetic properties, with concentrations of 71% in inhaled air resulting in anesthesia in 50% of patients. In human imaging, ^{129}Xe concentrations are typically limited to well below this value (whereas for ^3He MRI concentrations up to 100% in the inhaled gas are generally possible).

The large chemical shift between gaseous and dissolved ^{129}Xe of approximately 200 ppm allows selective RF irradiation of the dissolved phase. In chemical shift saturation recovery (CSSR) – a global spectroscopic method – this is used to selectively destroy the NMR signal arising from ^{129}Xe dissolved in tissue. Subsequently, a time series of global spectra is acquired, and the ratio of signal from dissolved phase and gas is monitored.

Initially this ratio is close to 0 because all signals from the dissolved phase have been selectively destroyed by RF. However, due to diffusive exchange between gas spaces and tissue, dissolved phase signal is recovered. Because HP ^{129}Xe is used, T_1 recovery to thermal polarization can be neglected, and all signals observed in the dissolved phase are due to ^{129}Xe atoms that have diffused from gas spaces into tissue.

Models of this recovery process exist, which aim to derive physiological parameters, such as alveolar surface area per gas volume (S_A/V_{gas}) and septal thickness, from the time course of signal recovery of the dissolved phase in a CSSR experiment.

Although CSSR is a promising method for *in vivo* measurement of pulmonary gas exchange parameters, it is a global method and does not yield regional information. In an imaging context, xenon polarization transfer contrast (XTC) has been proposed as a method being capable of regionally mapping gas exchange efficiency.

Similar to CSSR, XTC relies on selectively irradiating the dissolved phase to destroy its signal and monitoring its recovery. However, direct imaging of the dissolved phase in the lung is notoriously difficult, because only 2% of intrapulmonary ^{129}Xe is dissolved, whereas the gas phase constitutes 98%. Hence, instead of trying to image the recovery of the dissolved phase directly, XTC monitors the decay of the gas phase signal after selective destruction of the signal from the dissolved phase. This is done by acquisition of two images, one before and one

after selective irradiation. Then signal decay between both images can be quantified pixel-by-pixel. To account for the additional signal decay due to T_1 relaxation and RF pulse destruction, a control acquisition without selective irradiation of the dissolved phase is necessary.

XTC and CCSR are focused on gas exchange. Additionally, other methods have been proposed to image the dissolved phase directly, either by chemical shift imaging (CSI) or by a method termed xenon alveolar capillary transfer (XACT) imaging. The latter is based on the Dixon technique, and is even capable of distinguishing between signal arising from the red blood cells and the interstitial tissue barrier that separates blood vessels from the gas spaces. However, these methods have to deal with a low SNR, mostly due to the low partition coefficient of 0.02 between gas and dissolved phase.

Hyphenated NMR, Methods and Applications

Jerzy W Jaroszewski, University of Copenhagen, Copenhagen, Denmark

Introduction

Although NMR spectra of complex mixtures provide useful information regarding matrix composition and its variability, studies aimed at rigorous structure elucidation of low-molecular-weight organic compounds and requiring a range of 2D NMR experiments are best performed with pure compounds. Traditionally, such studies have been performed using 5 mm NMR tubes and milligram quantities of material purified in advance by some kind of chromatographic or physical separation technique. However, it is highly advantageous to combine a separation method and a spectroscopic measurement into one integrated technique, termed a hyphenated technique. The term thus describes a coupling of two (or more) analytical techniques into a multistage procedure in which an output from the first step is an input for the subsequent step(s). Hyphenated techniques are described by acronyms of the individual components of the system connected by hyphens; for example, GC-MS and LC-MS techniques, representing combination of mass spectrometry with gas and liquid chromatography, respectively, have a long-standing record of success in chemistry, biochemistry, and biology. Such hybrid techniques have the advantage of speed, of providing complementary analytical information from several techniques in one working process, and the ability to perform the analysis on very small samples.

Since NMR spectra supply particularly rich information with respect to structures of organic compounds, hyphenation of NMR spectroscopy with chromatographic techniques had already attracted attention in the late 1970s. However, magnetic resonance is intrinsically less insensitive than other common spectroscopic techniques and often operates on a different time scale in terms of measurement time. Thus, successful hyphenation of magnetic resonance with chromatography required a number of conceptual and technological challenges to be solved. Today, due to advances in NMR magnet and probe technology as well as software developments, hyphenated NMR (largely synonymous with HPLC-NMR) is a competitive technique capable of providing highly valuable results quickly and reliably.

Hyphenation of NMR Spectroscopy with High-Performance Liquid Chromatography: Direct Methods

In direct HPLC-NMR measurements, NMR spectra are acquired directly from the eluate of an HPLC column.

Reversed-phase HPLC columns are typically used with acetonitrile gradients in water as the mobile phase. If the HPLC separation is performed using nondeuterated solvents, peaks from these will dominate the NMR spectrum by a large factor making detection of dissolved analytes difficult. Although a number of effective solvent signal suppression techniques that resolve this dynamic range issue can be applied, their use will delete or diminish potentially significant solute resonances at the same or similar chemical shift values. In particular, the water NMR signal is broad, intense, and difficult to suppress. Therefore, HPLC separations for direct HPLC-NMR experiments are typically run using mixtures of deuterium oxide and nondeuterated acetonitrile, as use of fully deuterated mobile phase is expensive. Suppression of solvent resonances is preferably accompanied by ^{13}C -decoupling to eliminate ^{13}C satellites of the solvent signal.

Although a typical HPLC separation takes minutes or tens of minutes, many hours can be required to perform the necessary series of 2D NMR experiments. Thus, on-flow HPLC-NMR is rarely used. The problems with on-flow HPLC-NMR are due to a short residence time of the liquid in the detection volume of an NMR cell (e.g., for a flow rate of 0.8 ml min^{-1} the residence time for a $120\text{ }\mu\text{l}$ cell volume is 9 s). In addition to limited time available for spectra accumulation, the flow rate can reduce the effective T_2^* relaxation time, leading to signal broadening and reduced sensitivity. Solvent peak suppression becomes more difficult as saturated spins are continuously replaced with nonsaturated spins, and the suppression should be applied for as short time as possible. A partial solution to the sensitivity problem of on-flow HPLC-NMR experiments is to use larger HPLC columns (which allow higher analyte loading) and to reduce the flow rate substantially, but even then the experiment is capable of providing 1D NMR spectra of more abundant constituents only.

The solution to the above problems is stopped-flow HPLC-NMR, that is, temporarily halting the flow when the eluted compound of interest reaches the NMR probe. This of course requires an independent detection method (typically UV or MS) for correctly positioning the analyte elution band (peak) in the NMR probe, unless a series of stopped-flow experiments is performed in predefined time intervals over the whole elution time or a part thereof (time-sliced HPLC-NMR). However, stopping the flow will often compromise separation of the analytes still remaining on the HPLC column due to diffusion.

These problems are circumvented by use of the loop-storage technique, where the separated analyte bands (peaks) are directed to and retained in individual capillary loops, after which the solutions can be transferred one by one to the NMR spectrometer for NMR data acquisition. This format of hyphenated NMR provides an elegant solution to the time scale differences between the HPLC separations and NMR experiments.

In all direct HPLC-NMR experiments, the amounts of individual mixture components available for NMR are limited to what can be obtained from one injection of the mixture to the HPLC column. Thus, in order to achieve best results, the column loading should be maximized and the chromatographic separation optimized to achieve sharp peaks and thus maximal analyte concentration in the eluate. Moreover, the size of the NMR detector coil should match the peak elution volume.

Post-Column Solid Phase Extraction (SPE) in HPLC-NMR

The HPLC-SPE-NMR technique provides a substantial improvement of NMR hyphenation, not only in terms of sensitivity but also in terms of overall quality of NMR data. In HPLC-SPE-NMR, an automated solid-phase extraction (SPE) interface is placed online between the HPLC module and NMR spectrometer. When a chromatographic peak emerges from the HPLC column, the solvent flow is re-directed into a column (cartridge) containing an SPE material that will adsorb the analyte, while the mobile phase passes through to a waste container. Triggering of the SPE function can be achieved in a number of ways, including a threshold level of UV absorption of the HPLC eluate at various wavelengths (which can be selected differently for different peaks), MS signals, retention time, or by manual triggering. After this separation of analytes from the mobile phase (peak trapping), the SPE cartridges containing individual mixture components are dried with pressurized nitrogen gas, and the analytes desorbed (eluted) with a pure deuterated solvent for NMR data acquisition. Currently used are 2×10 mm and 1×10 mm SPE cartridges, which have bed volumes of about 30 and 8 μ l, respectively. This results in elution volumes considerably smaller than the size of elution volumes of HPLC peaks, resulting in analyte focusing. Obviously, the size of the SPE cartridge must match the size of the NMR cell. The NMR data can be acquired either with a flow probe or by means of microtubes, which have the advantage of preserving the solution for future use.

In addition to disjoining the chromatographic process from the NMR data acquisition in time, as is also the case for loop-storage HPLC-NMR, the HPLC-SPE-NMR experiment has several additional advantages. NMR

spectra are recorded with solutions in pure deuterated solvents rather than in a mixed HPLC mobile phase. Thus, reproducible chemical shift data from a well-defined solvent are obtained and only a considerably weaker residual solvent signal needs to be suppressed. Moreover, broad or distorted chromatographic peaks, which have a harmful effect on the outcome of direct HPLC-NMR experiments, may be acceptable in the HPLC-SPE-NMR format, as the underlying analyte will still be focused into the elution volume of the SPE cartridge. Finally and importantly, repeated trapping of a given peak on the same SPE cartridge can be performed, which can lead to a substantial increase of analyte amount available for NMR and thus reduction of data acquisition time. Therefore, the sensitivity of NMR hyphenation in this format is not restricted by the analyte amount from a single HPLC injection.

Current HPLC-SPE-NMR applications employ reversed-phase columns and reversed-phase SPE sorption mechanisms on bonded silica-based phases or polymeric resins. In order to increase the affinity of analytes to the SPE stationary phase, the HPLC eluate is diluted at least twofold with pure water by use of a postcolumn makeup pump in order to suppress its eluting power by diminishing the concentration of organic modifier in the mobile phase. Obviously, the success of an HPLC-SPE-NMR experiment is inherently dependent on the ability to perform successful postcolumn SPE of the analyte, and strongly polar analytes will escape extraction that utilizes the reversed-phase sorption mechanism. Attention should also be given to proper choice of deuterated solvent that will elute the compound from the SPE material to the NMR probe quantitatively and without tailing. Acetonitrile- d_3 is a nonviscous, general-purpose solvent generally used for SPE cartridge elution, although chloroform- d and methanol- d_4 are suitable solvents for nonpolar and more polar compounds, respectively.

The most serious limitation of current implementations of HPLC-SPE-NMR experiments is the inability to trap very polar compounds even after substantial postcolumn dilution of the HPLC eluate with water. Applicability of polar stationary SPE phases in connection with HPLC-SPE-NMR has yet to be explored.

Extended NMR Hyphenations

HPLC separations in HPLC-NMR are most commonly monitored by UV absorption of the column eluate, usually with a photodiode array (PDA) detector, and such HPLC-NMR systems are strictly speaking doubly hyphenated HPLC-PDA-NMR (or HPLC-UV-NMR) systems in case of direct hyphenation and HPLC-PDA-SPE-NMR systems when an SPE interface is included. The analyte flow passes through all devices sequentially.

In addition, the hyphenated NMR system very often includes a mass spectrometer that operates in parallel with a PDA detector. In addition to providing MS (and MSⁿ) data and detecting peaks of non-UV-absorbing constituents, the mass spectrometer can be used to govern stopped-flow experiments and to trigger loop collection or SPE trapping, either in total ion-current mode or in single-ion monitoring mode. An HPLC-DAD-MS-SPE-NMR system thus represents the state-of-the-art in NMR hyphenation, and a block diagram of such a system is shown in **Figure 1**. While in the past the stray field of NMR cryomagnets posed limitations with respect to physical proximity of components of a hyphenated system, in particular with respect to MS instruments, these concerns have been largely eliminated by the development of actively shielded magnets.

An extended hyphenated system may include other forms for spectroscopy such as FTIR or CD. Extended hyphenation (hyper-hyphenation) is sometimes termed 'hypeneration.' It should be emphasized that a true hyphenated system depends on integrated software that assures seamless control of the whole instrumentation.

Sensitivity Considerations in NMR Hyphenation

The main issue related to HPLC-NMR hyphenation is to achieve sufficient signal-to-noise ratio of the NMR signal with the amount of analyte deliverable by the chromatographic column. Apart from most simple cases of structure confirmation of expected compounds or their derivatives, hyphenated NMR experiments should be capable of providing satisfactory 2D NMR spectra, including one-bond and multiple-bond heteronuclear correlations and NOESY/ROESY spectra that are usually indispensable for structure elucidation of organic compounds.

Hyphenated NMR systems usually employ normal bore (4.6 mm i.d.) HPLC columns. Such columns can often be loaded with 1–2 mg of a mixture or more. Since NMR spectra can be acquired with analyte amounts in the low microgram range or even nanogram range (low-molecular-weight organic compounds), it is clear that these column loadings can provide sufficient amounts of minor mixture components for NMR data acquisition, depending on actual circumstances, type of equipment used, and kind of NMR experiment required. The ability to recognize and select a peak in an HPLC chromatogram determined by UV or MS response, in addition to HPLC resolution and NMR sensitivity, are important factors that determine the detectability threshold of HPLC-NMR experiments.

Optimization of sensitivity of hyphenated NMR experiments can be achieved in a number of ways. Magnetic field strength is of considerable importance, and 14.1 T magnets (corresponding to 600 MHz proton resonance frequency) offer a good compromise between cost and sensitivity. Probe design is of great importance, and advantage is taken from greatly improved mass sensitivity of miniaturized (1, 2, or 3 mm i.d.) transmitter/receiver coils. The actual probe-head size to be used in hyphenation mode is a compromise, the general goal being to encompass the whole amount of material delivered from an HPLC column into an NMR detection cell with maximized mass sensitivity.

Probes with cryogenically cooled transmitter/receiver coils and preamplifiers have increased sensitivity by a factor of about 4 compared to the corresponding room-temperature design and are available both for microtube and flow-through mode. Use of cryogenically cooled probes increases considerably real-time sensitivity for on-flow operations, as 4-fold improvement of sensitivity corresponds to 16-fold shorter acquisition time for multiscan data acquisition.

Figure 1 Schematic description of a hyphenated NMR system consisting of a liquid chromatography module (HPLC), photodiode array (PDA) detector, mass spectrometer (MS), and NMR spectrometer (NMR); solvent flow is indicated by solid arrows with alternative solvent paths 1–4 allowing on-flow, stopped-flow, loop-storage, or solid-phase extraction (SPE) operation modes. MP = mobile phase for HPLC separation.

The above-mentioned instrumentation represents vertical NMR cell design with Helmholtz (saddle) type coils. Solenoid-type microcoils with sensitive volume down to a fraction of microliter are also commercially available and are compatible with capillary HPLC. Hyphenation of capillary HPLC with capillary NMR is suitable for extremely mass-limited samples. However, the major area of application of capillary NMR probes is currently in combination with off-line separations.

An effective method of increasing NMR signal strength is increase of sample size. Therefore, analyte accumulation by multiple collection in HPLC-SPE-NMR mode is a very effective measure, provided that enough material for multiple injections to the HPLC column is available and that the analyte displays satisfactory properties with respect to SPE trapping. While still working in the microgram domain, doubling or multiplying the analyte amount in the NMR cell shortens the acquisition times and improves data quality considerably. An example of a practically linear analyte accumulation during repeated analyte collection in an HPLC-SPE-NMR experiment is shown in **Figure 2**.

^{13}C NMR chemical shifts are very important for structure determination of organic compounds, and such data are currently obtained from ^1H -detected heteronuclear correlation experiments. However, direct ^{13}C observation in hyphenation mode becomes feasible with cryogenic probes, especially probes with an observe channel optimized for carbon detection.

Other NMR Hyphenations

Even though HPLC is by far the most popular chromatographic technique, other chromatographic separation techniques can be hyphenated with NMR spectroscopy. Thus, reports on hyphenation of NMR with supercritical fluid chromatography, chromatography with superheated D_2O , ion-exchange chromatography, centrifugal partition chromatography, and gel permeation chromatography have been published. Developments towards hyphenation of NMR with electrodriven separations (capillary electrophoresis, isotachopheresis) and capillary gas chromatography have been reported. The two latter chromatographic techniques are characterized by excellent resolving power and are immediately compatible with solenoidal capillary NMR probes in terms of sample size. However, various technical difficulties with these types of NMR hyphenation have to be solved before they can be regarded as established analytical tools.

Applications

NMR hyphenation is applicable to analysis of all kinds of mixtures of low-molecular-weight organic compounds.

Figure 2 Improvement of signal-to-noise ratio in 1D NMR spectra of a natural product obtained in HPLC-SPE-NMR mode using a crude plant extract and repeated SPE collection on a polymeric stationary phase; n = number of SPE collections. For further details, see Lambert M, Stærk D, Hansen SH, Sairafianpour M, and Jaroszewski JW (2005). Rapid extract dereplication using HPLC-SPE-NMR: Analysis of isoflavonoids from *Smirnovia iranica*. *Journal of Natural Products* 68, 1500–1509.

Applications include food analysis; environmental analysis; metabolite and biomarker identification in connection with metabolomics, metabonomics, and metabolite profiling; drug metabolism; pharmaceutical analysis; and natural products research. The major advantage of use of hyphenated NMR techniques in these areas is the ability to perform structural elucidation of components present in complex mixtures while making isolation of compounds redundant.

Introduction

One of the most fascinating fields of instrumental development in mass spectrometry (MS) is hyphenation: the on-line coupling of various techniques to MS. Apart from the obvious combinations of straightforward coupling of gas chromatography (GC) or liquid chromatography (LC) to MS, a wide variety of other combinations has been described. This contribution pays attention to the rationale of hyphenated techniques and briefly indicates a number of typical applications.

The key idea behind hyphenation is the significant gain in signal-to-noise ratio, and thus improvement in detection limit, that can be achieved by multidimensional methods. This concept was nicely pictured by Yost and co-workers, in the early 1980s (**Figure 1**). While in hyphenation the response or signal achieved decreases with the increasing number of couplings or dimensions, the

(chemical) noise decreases even faster due to the increased selectivity, thus resulting in an improved signal-to-noise ratio. Another important issue is the ability to avoid sample losses and sample contamination in on-line rather than off-line combinations.

In principle, one can discriminate between various approaches to hyphenation, depending on the primary objective:

- (a) On-line separation technique coupled to MS, e.g. GC-MS and LC-MS.
- (b) On-line sample pretreatment in combination with a separation technique coupled to MS.
- (c) On-line multidimensional separation techniques coupled to MS.
- (d) On-line coupling of a separation technique to multiple detection strategies, one of which is MS.

Obviously, a combination of these strategies is also possible. Examples of these approaches are given below.

Figure 1 Hyphenation of analytical techniques. Dependence of the signal S , the noise N , and the signal-to-noise (S/N) ratio on the number of analytical stages.

Tandem Mass Spectrometry

The first hyphenated approach to be considered is the on-line combination of MS and MS, i.e. tandem mass spectrometry (MS-MS). A variety of combinations of different mass analysers have been described, including quadrupole and magnetic-sector analysers as MS_1 , and quadrupole, magnetic-sector, ion-trap and time-of-flight analysers as MS_2 . Instruments like triple-quadrupoles are widely used for MS-MS, either as stand-alone systems with sample introduction via a solids insertion probe or flow-injection analysis, or in on-line combination with GC or LC. The work of Yost and co-workers and of Hunt and colleagues exemplify these methods.

In the most common mode, i.e. the product-ion mode, MS_1 is used to select a precursor ion with a particular m/z from the variety of ions generated in the ion source. The mass selected ions are dissociated via collisions with an inert gas in a collision cell, and the product-ions are subsequently mass-analysed by MS_2 . In this setup, MS_1 can be considered as a separation technique, while MS_2 is operated as a conventional mass analyser and detector. Analogies between MS-MS and GC-MS have frequently been drawn (**Figure 2**). It has been argued whether a chromatographic separation is actually still required in a

Figure 2 Schematic comparison of MS-MS and GC-MS.

combination with MS-MS, given the excellent selectivity that can be achieved. However, it is currently generally agreed that some separation is required, at least in the analysis of samples of biological or environmental origin, in order to avoid rapid contamination of the ion source and in order to reduce and/or avoid analyte ion suppression effects, i.e. in electrospray ionization.

MS-MS is currently very widely used in combination with chromatographic separation methods, especially LC. The obvious reason for this is the frequent use of soft ionization techniques in LC-MS interfacing, i.e. electrospray and atmospheric-pressure chemical ionization. MS-MS allows additional structural information as well as the molecular mass information to be obtained. On-line LC-MS-MS is currently the method-of-choice in quantitative bioanalysis in (pre-)clinical pharmacological studies during drug development in pharmaceutical industries. In these studies, the instrument is operated in selective-reaction monitoring (SRM) mode, selecting a particular precursor ion in MS_1 and selecting and detecting one or more product ions in MS_2 . The excellent selectivity, the high level of confidence of identity, and the ability to use stable isotopically labelled internal standards are important arguments for the use of SRM in this type of routine applications.

On-line Chromatography–Mass Spectrometry

The on-line combination of a chromatographic separation technique (GC, LC, but also thin-layer chromatography (TLC), capillary zone electrophoresis (CZE) and supercritical fluid chromatography (SFC)) with MS enables the mass spectrometric characterization of components in complex mixtures after separation with minimal or no sample loss. It is especially useful in the identification of minor or trace components that are difficult to collect by fractionation of the column effluent or would be easily lost. Furthermore, as already indicated above, on-line GC-MS and LC-MS-MS are important tools in quantitative bioanalysis as well. Obviously, fractionation in large series

of samples for routine quantitative applications would be extremely time-consuming and ineffective.

GC-MS plays an important role in many application areas, including the characterization of components in petroleum and derived products and in essential oils, the identification and quantitation of compounds of environmental interest such as polychlorodibenzodioxins and related compounds, polycyclic aromatic hydrocarbons, pesticides and herbicides, and a variety of other microcontaminants. In addition, GC-MS is important in the analysis of compounds of pharmacological, forensic and/or toxicological interest, including drugs, anaesthetics, steroids, growth hormones and drugs of abuse.

LC-MS is applied in complementary fields, where the analytes are not amenable to GC-MS. LC-MS is for instance applied in the identification and quantitation of pesticides, herbicides, surfactants and (sulfonated) azo dyes in environmental samples, in the identification of drugs during drug development, their degradation products and metabolites, in the quantitative bioanalysis of drugs and related compounds in biological tissues and fluids, in the characterization of natural products, such as alkaloids, taxoids, toxins, as well as endogenous compounds like acylcarnitines, prostaglandins, and bile acids. Furthermore, LC-MS plays an important role in biochemical and biotechnological applications of MS, via the electrospray MS and electrospray LC-MS analysis of biomacromolecules like peptides, proteins and DNA fragments.

Methods and some applications of GC-MS and LC-MS are discussed in a separate contribution.

The on-line combination of TLC and MS via FAB, liquid SIMS, or MALDI has also been frequently described. The TLC-MS combination, reviewed by Somsen and co-workers, is applied for a wide variety of compounds, including drugs and their metabolites, antibiotics, steroids, alkaloids, lipids, bile acids, porphyrins, dyes and peptides.

On-line Sample Pretreatment

With the advent of LC-MS technologies, the on-line combination with various sample pretreatment strategies received considerable attention. The rationale for on-line sample pretreatment is to avoid sample losses and sample contamination during the off-line transfer from one step of the analytical procedure to another. In addition, an on-line procedure greatly facilitates automation of the complete procedure, thereby speeding up the analysis. The most successful and most widely applied approach is on-line solid-phase extraction (SPE) in combination with LC-MS. A number of instruments have been developed and commercialized for this combination, e.g. the Varian AASP, the Gilson ASPEC, the Spark Holland Prospekt,

and the Merck OSP-2. In all these automated systems, the sample constituents within a certain polarity range are trapped onto a short cartridge column (or Empore disk) containing reversed-phase LC packing material. The cartridge or disk may be washed with water to remove hydrophilic sample constituents. Subsequently, the analytes of interest are desorbed and transferred to an LC column for separation. These on-line SPE strategies serve for both sample pretreatment and analyte preconcentration. While on-line SPE-LC-MS was initially mainly developed for quantitative bioanalysis, the most important current application is in environmental analysis, i.e. in the selective sample pretreatment and analyte preconcentration of pesticides, their degradation products as well as other microcontaminants from surface water as an on-line part of the SPE-LC-MS or SPE-LC-MS-MS analysis. The results of the group of Brinkman show that analyte preconcentration by factors up to 10^3 or 10^4 are feasible in pesticide analysis from surface water, enabling concentration detection limits well below $0.1 \mu\text{g L}^{-1}$.

Consecutively, the same group demonstrated that SPE can also be applied in an on-line combination with GC-MS. An example is the SPE-GC-MS analysis of 10 mL of river Rhine water spiked at the $0.5 \mu\text{g L}^{-1}$ level with 80 microcontaminants, such as chlorobenzenes, aromatic compounds, anilines, phenols and organonitrogen and organophosphorus pesticides.

In addition to SPE, other sample pretreatment methods have been combined with GC-MS (see Goossens and co-workers), LC-MS or to MS(-MS) directly, e.g. on-line membrane sample introduction, solid-phase microextraction (SPME), supercritical fluid extraction and membrane dialysis.

A variety of on-line sample pretreatment procedures have been described for the coupling to on-line capillary zone electrophoresis (CZE)-MS, including capillary isotachopheresis, electrodialysis, liquid-liquid electroextraction and SPE on Empore disks. The latter system was applied to the analysis of the neuroleptic drug haloperidol in patients' urine by on-line Empore-disk SPE-CZE-MS.

Multidimensional Separation Techniques

Multidimensional separation techniques have been developed with a number of objectives such as increased peak capacity and/or improved resolution for the separation of highly complex samples, shortened analysis time via heartcut and partial analysis of fractions from complex samples, and enhanced detection of trace components. Both GC-GC, LC-GC, and LC-LC methods as well as various other multidimensional combinations involving CZE or SFC have been described and coupled to mass spectrometry. In most cases, the multidimensional approach

comprises a combination of two chromatographic columns, either containing two different stationary phases (both GC and LC), or developed with two different mobile phases (LC only). The sample is injected onto the first column. Part of the chromatogram is heartcut, either sampled onto a retention gap or short trapping column or transferred directly, and subsequently analysed on the second column, which is then interfaced to an MS. A typical setup for LC-LC-MS is shown in Figure 3.

Several examples of on-line multidimensional GC-MS were reviewed by Ragunathan and co-workers including the characterization of essential oils in order to determine the composition, to identify or quantify enantiomers, or to study the chemotaxonomy of the oil, and the determination of coplanar polychlorobiphenyl congeners.

The on-line combination of LC-GC-MS is applied in a variety of analytical problems, such as the analysis of (trace amounts of) aromatic compounds in complex fossil fuel fractions or in vegetable oil, the identification of microcontaminants in surface water, and the identification of impurities in pharmaceutical products.

The on-line combination of LC-LC-MS has been investigated for a number of reasons. In addition to the general prospects of multidimensional separation techniques, especially enhanced selectivity, there was special interest in the ability to perform LC-LC with two different mobile-phase compositions. In this way, it should be possible to avoid problems with mobile-phase incompatibility due to the use of nonvolatile mobile-phase constituents. A good example of this approach is the determination of enantiomers of β -blockers in plasma samples, described by Edholm and co-workers. Racemic mixtures of a β -blocker like metoprolol can be separated on a α_1 -acid glycoprotein column. However, the chromatography requires the use of a 20 mM phosphate buffer (pH 7) in the mobile phase, which is not compatible with on-line LC-MS. Therefore, the chiral column was coupled via a set of two trapping columns to a common reversed-phase LC column. After separation, the two enantiomers

Figure 3 Schematic diagram for a coupled-column LC-LC-MS system.

were separately trapped onto two short columns and subsequently transferred to the second LC column for analysis with a mobile phase containing ammonium acetate, which is well compatible with the thermospray LC-MS interfacing applied in this study. Subsequently, it was demonstrated that by the use of MS-MS the second separation step could be avoided: the effluent from the trapping column can be directly introduced into the MS-MS system, operated in SRM mode. This phase-system switching approach is well suited for solving this type of mobile-phase incompatibility problem.

Multiple Detection Strategies

The increasingly more difficult analytical problems to be solved is an important impetus in all developments in hyphenated techniques, but especially in multidimensional detection strategies. Development of adequate separation techniques for the analysis of complex samples is often a difficult task, independent of the question whether one is interested in only one compound present at trace level, or in characterization and structure elucidation of most sample components. Multidimensional separation techniques were developed in order to achieve the separation of the components of very complex samples. MS is an extremely powerful technique for the identification and structure elucidation of unknowns. The sensitivity of MS as a fairly universal technique in this area is unsurpassed. However, in many instances the information obtained from MS is not sufficient to enable unambiguous identification of the unknown compounds. Furthermore, in certain application areas it is obligatory to identify the components with such a high level of confidence that independent results from a second technique in addition to MS are required, as for instance for impurity screening of pharmaceutical products. Improved levels of confidence in identification and structure elucidation can be achieved by the use of multiple detection strategies. Although detection with a variety of detectors can be achieved via multiple analysis of the sample on systems equipped with different detectors, there has been a growing interest and need for systems which enable the use of multiple detectors coupled to a single analytical separation system. This is especially important in two areas, i.e. in the analysis of very complex samples where multiple detection strategies coupled to one single data-acquisition and processing system can greatly facilitate the interpretation of the data, and in the high throughput analysis where minimization of the analysis time is of utmost importance.

Several dual or multiple detection systems involving MS have been described. In this respect, one should not forget that the mass spectrometer is a destructive detector. Therefore, the mass spectrometer should be the final

detector in a series. Combination with another destructive detector, e.g. a flame ionization detector, is possible only after splitting the column effluent, while in-line coupling with a non-destructive detector, e.g. a UV absorbance detector, is only possible when this detector does not result in too much chromatographic peak broadening. In several cases, the second nondestructive detector is used in parallel rather than in series, e.g. because the sensitivities of both detectors are widely different, or in order to avoid the loss of chromatographic resolution due to excessive peak broadening by the first detector in the series. The most widely applied dual detector strategies are those where MS is combined with another spectrometric technique, in order to obtain complementary structural information. The direct coupling of LC with both NMR spectroscopy and MS in parallel has been widely used in the analysis of pharmaceutical compounds and for elucidation of the structures of drug metabolites.

Two types of spectrometric detectors have been widely used in an in-line combination with GC-MS, i.e. Fourier-transform infrared (FT-IR) and atomic emission spectrometry (AED). Both FT-IR and AED are used in parallel with the MS, i.e. after a split.

GC-FT-IR-MS systems are commercially available. When the measured IR spectrum of an unknown is not present in the IR spectral library, the FT-IR part of the system can help in the identification of an unknown by providing information on functional groups and the structural backbone. While homologues cannot readily be identified from IR spectra but easily discriminated by MS, the FT-IR part can be used as an important tool in discriminating between structural isomers where MS generally fails. Typical applications of GC-FT-IR-MS can be found in the analysis of essential oils, flavours and fragrances, and in the identification of isomeric reaction products or other types of isomeric compounds. The potential of a dual detection GC-FT-IR-MS system was also explored for the identification of illicit drugs, e.g. in tracing banned stimulants used by athletes.

The combination of GC-AED-MS to our knowledge is not (yet) commercially available. The element specificity of the AED can be of great help in identifying particular classes of compounds in complex samples, e.g. in environmental screening. The AED provides information on the presence of certain elements, e.g. halogens, nitrogen, or phosphorus, in the chromatographic peaks detected. This facilitates the search for relevant peaks as well as the interpretation of the mass spectra of particular compounds in a complex chromatogram. In addition, the AED can provide a fairly accurate determination of the elemental composition, thereby often excluding the need for accurate mass determination by expensive magnetic sector instruments. Furthermore, GC-AED-MS can be applied in the analysis of organometallic compounds, e.g. organomercury and organotin compounds.

The availability of nondestructive flow-through detectors for LC, e.g. UV absorbance and fluorescence detectors, readily leads to the application of dual detection systems in LC-MS. While the additional information of single-wavelength UV detection is generally limited, the availability of efficient and sufficiently sensitive UV-photodiode array detectors enables the on-line acquisition of UV spectra as well as mass spectra (**Figure 4**). Although the structural information available from a UV spectrum is generally limited, especially in a relatively undefined solvent mixture during gradient elution, the on-line combination can successfully be used in facilitating identification when appropriate UV spectral libraries are available. The combination of retention time in a well-defined LC system, the match of a UV spectrum, and the molecular mass (and possible structural information) from MS are especially useful for confirmation of identity, e.g. in multiresidue screening for pesticides in environmental samples or antibiotics in food products. Furthermore, an excellent feature of UV-PDA i.e. diode array systems in combination with appropriate software is peak purity assessment, based on changes of the UV spectra over the chromatographic peak. This feature may be helpful in impurity profiling by LC-UV-PDA-MS.

Although the use of FT-IR in combination with LC is of growing importance, the on-line or in-line combination of FT-IR and MS is not yet frequently applied. However,

the on-line combination of LC-MS and NMR has gained acceptance as an important tool in identification of impurities, degradation products, and/or metabolites of pharmaceutical products. One example of on-line LC-NMR-MS is the characterization of ibuprofen metabolites in human urine. Simultaneous acquisition of electrospray MS and NMR spectra of synthetic drug products in an 'open-access' setting has also been reported.

Final Considerations and Perspectives

Hyphenation in relation to MS is an important research topic because in many instances the optimum tuning of the two or more parts of the setup requires considerable attention. Good knowledge of both parts is required in order to avoid the often inevitable compatibility problems and to obtain best possible results. However, hyphenated MS techniques have already widely proved their value in solving real analytical problems.

In principle, the use of advanced data-processing software could be considered as a hyphenated approach as well, but in general is not. However, one can question whether the use of principal component analysis and similar data-processing techniques does not have a similar impact on the analytical procedure and its result as the hardware hyphenation discussed above.

Figure 4 An example of typical results from an LC-UV-PDA-MS setup for dual detection of separated compounds.

Software for both controlling the hyphenated combination of techniques and efficient processing of the data is of utmost importance to the breakthrough and general use of a hyphenated technique. In this respect, the development of automatic tuning and calibration software for GC-MS and more recently LC-MS, of computer spectral library searching after electron ionization, and of efficient quantitation software packages after both GC-MS and LC-MS can be considered as important steps in the development of hyphenated techniques. Control of the complete (often multivendor) instrumentation, including the GC or LC chromatograph, the sample processor or autosampler, on-line or off-line second (scanning) detectors from within a single software platform, often the MS control and acquisition software, is also essential and obligatory for the success of the technique. Some instruments enable high levels of automation and control via the use of macro scripts or instrument control languages. Such approaches may be used for optimization and/or control of the various steps in the hyphenated technique, but also for artificial-intelligence type of applications where the software makes decisions concerning the analytical strategy to follow or the type of experiments to perform on the basis of the data acquired. The latter is, for instance, applied in data-dependent product-ion scanning during GC-MS-MS and LC-MS-MS.

Progress is also made in software for mass spectral interpretation, especially for the so-called deconvolution of (mixed) ion envelopes of multiply charged protein ions generated by electrospray ionization, and for the peptide sequencing by MS-MS techniques. In that respect, the development of tools to search extensive protein and DNA databases using peptide maps, peptide molecular masses, LC retention time data, and sequence tags is an enormous step forward in the routine application of hyphenated MS-MS.

Excellent examples of the hybrid of hyphenated hardware, automated sample processing via computer control of the instrumentation, and automated data processing can be found in approaches developed in relation to combinatorial chemistry. In order to screen a particular combinatorial library in a 96-well plate, high throughput electrospray LC-MS is applied. The data are post-processed by means of a browser, which compares the molecular mass measured with expected values, taking into account the various cationized and anionized species that may be generated during electrospray ionization. By means of green and red colours, the software indicates on a screen representation of the 96-well plate which samples were found to be present and which were not. In addition to this, and using similar software strategies, the use of automated fraction collection after preparative LC

under control of the data acquired by MS has been demonstrated. This hyphenated approach allows the purification of particular products from extensive combinatorial libraries based on the results of a first biological screening and prior to a more advanced biological screening, using the purified products.

Introduction

Inductively coupled plasma mass spectrometry (ICP-MS) combines the well-accepted high-energy inductively coupled radio frequency (RF) plasma source with mass spectrometers to produce both elemental and isotopic analyzers in the same instrument. The growing worldwide popularity of ICP-MS, since the early 1980s, stems from the unique properties of the ICP enhanced particle–plasma interaction in the axial column, resulting in reduced matrix effects, multielement capability, enhanced sub-nanogram per liter limits of detection (LODs) (over 90% of the elements in the periodic table can be determined in aqueous solutions), robustness of the instrumentation, and convenience provided by easy-to-use software. However, in real sample analysis, the matrix frequently poses a challenge to accurate analysis. This has been partially solved using advanced sample introduction strategies and solution dilution in the case of high ion transmission spectrometers.

ICP-MS plays an increasing role in clinical, geo- and enviroanalysis, geochemistry, and isotope studies. It provides a convenient way to determine sub-nanogram per liter concentration levels of low-abundance elements and metal speciation. It is irreplaceable for studying trace element influx in hydrological systems, element migration in waste disposal depositories, soil horizons, aquifers, the marine environment, and biological uptake. Owing to the excellent precision and accuracy of ICP multicollector MS (ICP-MCMS), it is becoming the established method for accurate isotope ratio measurements with liquid sample introduction and direct solids analysis.

Readers wishing to expand their knowledge on ICP-MS applications can refer to the following journals:

Analytical Chemistry, Analytical Chimica Acta, Applied Spectroscopy, Applied Spectroscopy Reviews, Atomic Spectroscopy, Canadian Journal of Analytical Sciences and Spectroscopy, Chemical Geology, Critical Reviews in Analytical Chemistry, Fresenius' Journal of Analytical Chemistry, Journal of Analytical Atomic Spectrometry, Journal of the American Society for Mass Spectrometry, Microchemical Journal, Spectrochimica Acta Part B, Spectroscopy, Talanta, Trends in Analytical Chemistry, and annual reviews in the Journal of Analytical Atomic Spectrometry (Atomic Spectrometry Updates) and in Analytical Chemistry, which includes sections on instrumentation, methodology, and fundamental aspects and applications.

Performance Capabilities of ICP-QMS versus SF-ICP-MS

There are three main instrumental approaches that are used for the myriad of applications: quadrupole (Q), sector field (SF), and multicollector (MC) ICP mass spectrometers. A major disadvantage of inductively coupled plasma quadrupole mass spectrometry (ICP-QMS) is the limited capability of resolving polyatomic ions that interfere with analyte ions. Although collision and reaction cells reduce molecular ion interferences, high-resolution sector field ICP-MS (ICP-SFMS) has a distinct advantage over ICP-QMS because of much higher signal response and its ability to resolve spectroscopic interferences. Although sensitivity is inversely related to mass resolution and ion transmission efficiency, the loss in signal is not significant in comparison to ICP-QMS. Because of the multielement picogram per liter LODs of ICP-SFMS, these types of instruments have a distinct advantage for ultra trace element determinations in complex samples, in pristine and clinical samples, and in speciation analysis. A further advantage of ICP-SFMS is excellent accuracy of data obtained without resorting to tedious and contamination-prone preconcentration and matrix separation procedures, and the complexity of applying collision–reaction technology. An additional advantage of these high-sensitive instruments is that although it is not feasible to directly analyze solutions containing 10–20% total salt concentrations, a 1000–5000-fold dilution allows determination of many low concentration metals of interest.

Although the cost of these instruments is considerably higher, they produce accurate data in comparison to collision–reaction cell technologies.

High-Precision Isotope Ratio Applications

Although there has been considerable debate on the precision and accuracy of ICP-MCMS compared to thermal ionization mass spectrometry (TIMS), the former has

become an accepted technique for accurate determination of isotope compositions for geochronology, fingerprinting ancient and modern geological processes, and stable isotope tracers to evaluate metal migration and speciation in the environment. Until recently, TIMS was exclusively employed for accurate and precise isotope ratio determinations. The ICP was considered to be unsuitable due to plasma flicker noise, and turbulence in the nebulizer and spray chamber. However, recent data using ICP-MCMS indicate that poor relative standard deviations (RSDs) using ICP-QMS are mainly due to electronic and thermal instability of the instrument and to temporal differences in the measurement and that these instabilities can be compensated for using multicollection techniques.

With the rapidly growing improvement of ICP-MCMS, the application of the ICP for isotopic analysis is expanding. Sample preparation is relatively straightforward, sample throughput is high, operation is convenient, and accuracy and precision ($\sim 0.01\%$) is competitive with TIMS. With the use of ICP-MCMS, measurements on large numbers of samples can be made in comparison to the very small number of samples that can be analyzed using TIMS. ICP-MCMS has been demonstrated to be capable of determining accurate isotope ratios not only in solutions but also in solids using laser ablation (LA). Three methods for correction of mass bias are effectively employed (standard reference materials, internal normalization, and ID).

Spectroscopic Interferences–Polyatomic Ions

Although most elements have at least one isotope that is free from overlap by isobaric interferences, in practical analysis, coincident polyatomic doubly charged ions (observed at half the mass), and plasma and sample-derived ions are serious obstacles in the application of ICP-QMS. These molecular species are derived from ion–molecule interactions of the matrix, solvent and decomposition and sample modification reagents with the Ar plasma support gas, entrained atmospheric nitrogen and oxygen. They are formed in the plasma during ion sampling and extraction in the interface, in the plasma–sampler cone interface, and in the supersonic region between the cone and the skimmer–ion optic regions. In particular, Cl-based interferences have serious implications on sample decomposition routines using HCl and HClO₄, for example, $^{35}\text{Cl}^{16}\text{O}^+$, $^{40}\text{Ar}^{35}\text{Cl}^+$, and $^{40}\text{Ar}^{37}\text{Cl}^+$ for the determination of $^{51}\text{V}^+$, $^{75}\text{As}^+$, and $^{77}\text{Se}^+$, respectively. Among the most influential oxide interferences are those of CaO^+ on Ni, and $^{59}\text{Co}^+$, of $^{135}\text{Ba}^{16}\text{O}^+$ and $^{137}\text{Ba}^{16}\text{O}^+$ on $^{151}\text{Eu}^+$ and $^{153}\text{Eu}^+$, and light rare earth elements (LREEs)-O⁺ on heavy lanthanides heavy rare earth elements (HREEs). From the practical aspect, polyatomic and doubly charged ions

result in substantial degradation of LODs and accuracy. Several approaches have been adopted to reduce polyatomic interferences.

Collision–Reaction Cells

Recent developments in collision and dynamic reaction cells (DRCs) have indicated that many isobaric polyatomic interference signals can be attenuated using pressurized collision cells and reaction chambers.

In the Perkin Elmer-Sciex DRC, the cell is pressurized with reactive or collision gases such as ammonia, methane, or oxygen. A RF quadrupole ion guide discriminates against unwanted ions and reaction products by limiting the band pass through the cell. The limiting parameters are RPq and RPa cutoff voltages (q and a parameters from the Mathieu equation).

The critical disadvantage of the DRC is the optimization for different reaction gases and cell operating conditions for given elements in unknown matrices. Selection of the RPq and RPa parameters results in rejection of ions that could form additional polyatomic ions in the cell. These in-cell interferences must always be taken into account when considering any cell gas. However, formation of new ions in the cell can be advantageous. For example, by using O₂ or F in the reaction cell, analyte ions of interest can be converted to non-interfered M–O⁺ and M–F⁺ ions.

In the Agilent 7500 and Thermo X-SERIES, non-reactive gases such as helium can be used with kinetic energy discrimination (KED) to prevent unwanted species reaching the quadrupole mass analyzer. Polyatomic ions generated in the plasma, in the interface, and in the cell, have larger atomic radii than analyte ions of similar mass and statistically collide with helium atoms more frequently and consequently lose more energy. In KED, an energy barrier (bias) is created between the collision cell and the quadrupole filter preventing these ions from entering the quadrupole mass filter. Because these molecular ions have lower kinetic energies than the analyte ions, the application of a positive retarding hexapole dc bias potential suppresses their signals by at least three orders of magnitude whereas most of the analyte ions are transmitted with very small reductions in response. The use of a single nonreactive gas (helium or xenon) removes numerous molecular interferences that hinder determination of common trace elements. In addition, these instruments can employ reactive gases such as H₂ and O₂ to remove interferences via beneficial ion–molecule reactions.

In the Varian system, molecular ion interferences are reduced using a different mechanism. These ions are removed in a collision–reaction interface (CRI) by injecting a collisional gas (He), or a reactive gas (H₂), or a mixture, directly into the plasma (whether this is the real ICP or an extracted beam is a subject of fundamental interest) as it

flows through the skimmer and sampler cone orifices; that is, this configuration suppresses molecular ion interferences before they are extracted into the ion optics.

Nonspectroscopic Interferences

Nonspectroscopic interferences (also called matrix effects), resulting in suppression or enhancement of analyte signal, may be derived during sample introduction, in the plasma, in the interface, and in the mass spectrometer. The effect of high salt concentrations is reduced by dilution, which can be performed on-line using flow injection. However, there is a limit to dilution because of the reduction in limits of determination and contamination.

Space Charge Effects

In space charge effects, high concentrations of a heavy matrix element can cause depression of light analyte ion signals. Lighter ions are deflected out of the beam because they have less momentum, that is, a heavy matrix impedes the movement of light ions as the ion cloud enters the zone between the sampling cone and the skimmer and ion optics.

Mass-Dependent Signal Depressions

Matrix-induced suppression is the largest source of interference when relatively concentrated samples are nebulized. There are several processes that can cause mass-dependent signal variations when solutions containing moderate concentrations of Na and Ca are nebulized. These effects are attributed mainly to salt deposition on sampler and skimmer cones and ionization suppression caused by easily ionized elements (EIEs) in the plasma.

Sample Preparation

ICP-MS is first and foremost a solution-based technique. There are several advantages in the preparation of solutions:

- Elimination of mineralogical properties and grain size differences.
- Utilization of large amounts of sample minimizes effects of original solid sample heterogeneity and mineralogy.
- Sample matrices can be matched more readily in the solution form.
- Partial dissolution strategies can be adopted for element speciation by extracting specific mineral species and metal–organic complexes. The composition of the labile extractable fraction can be used to identify sources and process of migration and sedimentation.

However, there are several disadvantages of solution analysis:

- Numerous chemically resistant silicate and oxide minerals and high technology metals and alloys are not totally dissolved, resulting in less than 100% recoveries.
- The total salt concentration in solutions should not exceed 0.1% to prevent salt deposition on the interface cones and to minimize matrix-related interferences.
- Dilution of high salt solutions degrades limits of determination.

Fusions and Sinters

One of the setbacks in ICP-MS is the necessity of restricting the total salt content of the aspirated solution to not more than 0.1%. Thus, when alkali fusions and sinters are used in ICP-MS, the solution has to be diluted an additional 25–50 times (in total 2500–5000) to avoid salt deposition on the sampler and skimmer cones. Nevertheless, there are several advantages of sodium peroxide as a fusion agent. It is highly reactive and oxidizing and the recoveries of the W, Cr, Nb, Ta, and the REEs are excellent. Most refractory silicates are rapidly decomposed even at a sinter temperature of approximately 450 °C.

When high-temperature Li-borate fusions are used, it should be emphasized that most volatile elements are lost (As, Se, Pb, Cd) and the serious memory effect of B should be taken into account. However, recoveries of high-field strength elements (HFSE – Zr, Y, Ti, Nb, Ta, and Hf) and Cr, which are located in chemically resistant mineral phases, are high.

Mixed Acids Containing HF

Although mixed acid low-pressure digestions in polypropylene and perfluoralkoxy (PFA) bottles are widely used for the digestion of silicate rocks and environmental samples for trace element and isotope ratio determinations, most mixed acid (HF, HNO₃, HClO₄, HCl) procedures are conducted in microwave ovens. There are several disadvantages of using these methods: Numerous chemically resistant ceramics, minerals, and metallurgical samples are only partially decomposed using mixed acid techniques; for example, aluminosilicates, spinel, and Ti- and Cr-bearing Fe oxides. As a result Al, Cr, HFSE, and REEs recoveries can be unsatisfactory.

Excess HF is removed by evaporation with HClO₄ – an extremely hazardous undertaking when organic matter is present due to the explosive reaction. Notwithstanding the disadvantages of HF-mixed acid procedures, there are several advantages:

- In comparison to fusions, the salt concentration of the solution is relatively low, and as a result of the smaller

dilution, limits of determination are better than those obtained with fusion procedures.

- The use of high-purity acids results in lower levels of contamination.

Partial Digestion

Although there is considerable debate on the validity of sequential extraction, for example, the Tessier and BCR partial digestion procedures (Bureau of Reference of the Commission of European Communities, presently administered by the Institute of Reference Materials and Measurements (IRMM)) are widely used to determine the mode of occurrence of the analyte species in sludge, sediments and soils, and in geochemical exploration. Tessier developed several protocols by which various fractions could be selectively extracted:

- 'Exchangeable' fraction provided by 1 M MgCl₂ at pH 7.
- The 'carbonate' fraction by 1 M Na acetate at pH 5.
- The 'Fe-Mn oxy-hydroxide' fraction with 0.04 M hydroxylamine hydrochloride in 25% acetic acid.
- The 'organic' fraction with 0.02 M HNO₃ and 30% H₂O₂ at pH 2; then 3.2 M ammonium acetate in 20% HNO₃.
- The 'residual' fraction is obtained by a mixed acid HF–HClO₄ digestion.

Direct Solids Analysis

Several direct solids analysis techniques overcome the problems of sample preparation: slurry nebulization (SN), LA (described in a separate article in this volume), electrothermal vaporization (ETV), direct sample insertion (DSI), and field-flow fractionation (FFF), in particular, sedimentation field-flow fractionation (SdFFF). One of the major and common problems of these techniques is particle–plasma interactions giving rise to interference effects that are influenced by particle size, mineralogy, and chemical composition of the solid mineral particles. Moreover, since most of the techniques involve some kind of thermal processes, it can be anticipated that constituent refractory minerals undergo differential thermochemical reactions, resulting in element fractionation.

Direct Analysis of Suspensions

The main advantage of SN ICP-MS is the negligible cost of the equipment and the analysis, since no additional equipment is required other than the need for a high solids nebulizer capable of delivering the suspensions to the spray chamber without clogging. However, different solid samples have different atomization efficiencies and as a result analyte recoveries vary widely due to particle–plasma interactions and transport effects that are

functions of sample chemistry and mineralogy and the size of the solid suspended particles. Consequently, particles $> 1\mu\text{m}$ do not behave like aqueous aerosols and as a result calibration curves based on aqueous solutions are not identical to those of the slurries.

Electrothermal Vaporization

As in graphite furnace atomic absorption spectroscopy (GFAAS), in ETV-ICP- atomic emission spectrometry (AES), multistep time-controlled furnace temperature programs are deployed to transform the solution to a solid phase, and subsequently differentiate the different vaporization of samples and analyte species of interest. Fractional vaporization of volatile versus involatile elements is used with advantage to overcome polyatomic ion and isobaric interferences; volatile elements (e.g., Cd, Pb, Cu, As, Se, Bi, Tl, Zn) are vaporized at 1000–1500 °C, involatile elements (e.g., Mn, Cu, Co, Fe, Ni, Sr, Ba, U) at 2000–2500 °C, and refractory elements (Al, Mo, Cr, Zr, W, Nb, Ti, REEs) at 2700–3000 °C. Metal species can be differentiated by temperature programming.

Samples containing organic matter, moisture, and other undesirable volatile components can be eliminated when the ETV is used as a thermochemical reactor for sample pretreatment. In this approach, the tandem coupling of the ETV to the ICP is used to remove volatile components, acids, and solvents during an initial lower temperature drying step, resulting in reduction of interfering polyatomic ions derived from the digestion reagents and the sample itself.

Solid biological samples (tissues, hair, milk, and vegetation) are analyzed by ETV-ICP-MS. A solution or slurry is prepared by mixing a small sample aliquot ($< 100\text{mg}$) with a small volume (10–200 μl) of a 25% m/v tetramethylammonium hydroxide (TMAH, a very strong base) solution. A suitable modifier is added, and the mixture placed into a carbon or tungsten boat. Solid samples are also analyzed directly using ETV-ICP-MS. Small amounts of homogeneous sample are weighed, mixed with modifier and vaporized in the ETV. Solid samples can also be pumped into the ETV in the form of a slurry. However, sample heterogeneity and grain size should be taken into account. External calibration with solid standards of similar composition (certified reference materials, CRMs) to the samples produces accurate results.

The advantage of ETV-ICP-MS is that the technique efficiently handles solutions containing very high dissolved solids and has the ability to analyze very small amounts of organic matrices, forensic, radioactive, and toxic materials. A result of water removal is the reduction in H- and O-based polyatomic ion interferences. Although the signals of numerous matrix-induced polyatomic ions are reduced, C-based molecules derived from carbon particles from the carbon cuvette persist.

Direct Insertion

In this technique, the dried and pyrolyzed sample, mounted in an electrode cup, is inserted into the ICP via the injector tube of a modified torch. A microprocessor controls the position of the graphite rod with a stepper motor, and drying, pyrolyzing, and thermal atomization stages can be programmed. As in the case of ETV-ICP-MS, the sample can be desolvated and volatile organic components eliminated *in situ* by inductively heating the electrode in the induction region of the load coil while applying a low RF power ($\sim 50\text{ W}$).

Field-Flow Fractionation

FFF provides information on the size distribution of particles; in particular, SdFFF separates soluble and colloidal components over a wide size range from a few nanometers to a few micrometers. When coupled to ICP-MS, SdFFF produces element-based particle size distributions of colloidal samples. Important information on the role and composition of colloidal and recently nanoformations in the environment is gained.

Vapor Generation

The problems associated with liquid sample introduction and inefficiencies in analyte transport can be overcome by presenting the analyte to the plasma in the gaseous form. A hydride generator includes facilities for on-line mixing, reaction, and gas-liquid separation. In hydride generation (HG), gaseous hydride species of certain analytes (As, Sn, Pb, Sb, Bi, Ge, Se, and Te) are formed in the reaction with acidic sodium borohydride (sodium tetrahydroborate, NaBH_4).

A big advantage of chemical vaporization is the separation of the analyte as a volatile species from the sample, obtaining near 100% analyte transport efficiency, resulting in improved detection limits and elimination of spectroscopic and nonspectroscopic matrix interferences. The LODs vary from 0.01 to 0.1 ng l^{-1} , one order of magnitude improvement compared to conventional solution nebulization with no HG. Unfortunately, hydride reaction conditions are not the same for all hydride-forming elements, thereby constraining simultaneous determinations. In addition to favorable LODs, HG-ICP-MS eliminates matrix-derived spectroscopic interferences, for example, elimination of $^{40}\text{Ar}^{35}\text{Cl}^+$ on ^{75}As and front-end effects caused by a high salt matrix. An important application of HG-ICP-MS is the determination of As and Se.

A dual hydride-forming nebulizer (multimode sample introduction system (MSIS)) allows simultaneous determination of hydride and nonhydride-forming elements. The nebulizer consists of a high solids V-groove nebulizer, with two separate solution channels for simultaneous delivery of sample and NaBH_4 reducing

solution. Both gaseous reaction products and liquid aerosol are introduced into the ICP-MS with the added benefit that the nonhydride-forming elements (e.g., Mg, Mn, Mo, Ni, Co, Cu, Zn, and Cd) can also be determined simultaneously under hydride-forming conditions with nanogram per liter detection limits. Chemical effects by transition elements (e.g., Ni, Co, and Cu) that cause signal suppression of hydride-forming elements can be countered by adding ethylene-diaminetetraacetic acid (EDTA) as a masking agent.

Matrix Separation–Analyte Preconcentration

When the concentration of trace elements of interest is in the nanogram per liter level and the solution contains high dissolved solids concentrations, such as seawater, saline springs, soil and rock digestions, and clinical samples, trace element determinations are mitigated by a wide range of spectroscopic and nonspectroscopic interference effects. High concentrations of EIEs (Na, K, Li, Ca, and Mg) distort the normal distribution of excited ion and atom species in the plasma zone used for multielement analysis. Interference effects also occur in the interface region between the ICP and the sampling cone and skimmer of the mass spectrometer. The presence of high salt causes orifice blockage, resulting in a variable change of sensitivity. Furthermore, the introduction of solutions containing salt concentrations can result in interferences in aerosol generation and transport systems.

There are several limitations that should be taken into account: Chelating resins cannot concentrate trace elements quantitatively if they occur as metal–organic complexes. Organic solvents interfere in aerosol generation and transport systems, reduce plasma robustness due to plasma cooling, change plasma ionization, and deposit carbon in the torch and in the MS interface.

Speciation

The combination of liquid and gas chromatography (LC and GC) with ICP-MS is widely applied as a sensitive detector for metal speciation studies. In environmental, clinical, and nutrition studies, there is a growing requirement to provide, not only data on the abundance of an element in a sample but also on its form and how it is associated with other elements and minerals.

One of the serious setbacks, commonly overlooked in speciation analysis, is the critical requirement to preserve species integrity from the sampling site to transport, preservation, pretreatment, detection, and validation of determined results. This is a serious limitation because many species are reactive and are rapidly transformed to other species during sampling, storage, and measurement.

Enhanced methods, such as microwaves, ultrasound, and enzyme-assisted extraction, can result in species degradation and transformation.

Liquid Chromatography

Coupling is simple because LC flow rates are compatible with the nebulizers used, and as a result, the effluent from the LC separation column is transferred into the aerosol generation system. The use of low-consumption nebulizers and small volume spray chambers conserves sample consumption and avoids band broadening. LC mobile phases contain combinations of organic solvents, buffer solutions, and ion-pair reagents in relatively high concentration. These constituents cause instability in the plasma and physical blockage of the sampling cone and nebulizer. Use of water-cooled spray chambers, increase in RF power, and addition of oxygen to the nebulizer gas flow reduce these problems. In addition, when organic solvents are employed, the solvent load is reduced by lowering consumption using a low-consumption microconcentric nebulizer, with a low-volume water-cooled spray chamber, with membrane desolvation, and adding oxygen to the plasma gases.

Speciated Isotope Dilution

Speciated isotope dilution ICP MS (SID-ICP-MS) uses speciated isotope spikes to determine the quantity of the species in the sample and to correct for species conversion that could occur during sampling, preservation sample preparation, species extraction, and analysis. SID-ICP-MS corrects for species transformation during extraction and the measurement process.

Ideally, the optimum ratio of the isotope pair should be close to unity. Addition of the isotopic spike compensates for analyte loss, physical and chemical interferences, and nonquantitative derivatization during sample preparation. Given that the natural abundance of the isotope in the sample and in the spike is known, the analyte concentration in the sample can be calculated. It is assumed that the spike is in equilibrium with the analyte in the sample and that both behave in an identical way. One of the factors influencing this procedure is correction for mass bias in the MS measurement. Since mass bias correction factors can significantly vary in each chromatographic run, this correction should be made simultaneously throughout the analysis sequence.

Gas Chromatography

GC-ICP-MS is widely employed for the determination of volatile species. The coupling of a GC to an ICP-MS is achieved via a temperature-controlled, insulated transfer line consisting of a heated multicapillary microcolumn bundle – heated to ensure preservation of the thermally

stable, volatile species (or derivatized compounds) en route to the plasma. Although a makeup gas reduces sensitivity, its use facilitates the introduction of the effluent into the ICP.

In speciated isotope dilution gas chromatography inductively coupled plasma mass spectrometry (SID-GC-ICP-MS), an isotopically labeled spike in the exact form of the analyte species is accurately spiked into the sample and the standards.

Calibration and Quantification

Several calibration strategies are used to correct for matrix effects and instrumental variations.

Matrix-Matched External Calibration

The composition of the calibration standards with respect to bulk constituents and acid concentrations are matched to those of the samples. It should be emphasized that matrix matching of environmental and geological samples is difficult owing to very wide range of composition.

Method of Standard Addition

The standard addition method is used to verify analytical results of complex samples exhibiting matrix effects. The sample is split accurately into several aliquots, and spiked with different concentration levels of the elements of interest. A linear function between the spiked concentrations and the ion signals is calculated. The concentration of the unknown sample is given by the X-intercept.

Internal Standards

Signal variations occur due to changes in the sample introduction and aerosol transport systems, the plasma and the plasma-mass spectrometer interface. In addition to instrument drift, internal standardization is effective in correcting for all these interferences. The following criteria are used for selecting internal standards:

- Free from polyatomic ion interferences. When using collision-reaction cells, internal standards must behave in the same way as the ions being measured taking into consideration both focusing and scattering.
- Similar ionization potentials. In the case of As and Se, that is, elements with a high ionization potential, an element with a similarly high ionization potential must be used to compensate for the enhancement effect of carbon-containing compounds.
- Chemical compatibility with the matrix.
- The internal standard elements are not present in detectable concentrations in the samples and in the standards.

Isotope Dilution

ID is the ideal internal standard because a selected element of known isotope composition is spiked into the sample solution. Accordingly, provided ion responses are high and similar, the effect of matrix-induced signal suppressions on ion signals is compensated and excellent precision ($<0.5\%$) and accuracy are obtained. If equilibrated with the sample, losses during sample preparation (species transformation, precipitation, etc.) can be calculated. By measuring isotope ratios of the sample and sample + spike isotope addition and given the isotopic ratio of the enhanced spike, sample concentrations can be calculated. The ID method is considered to be a *definitive* method and is used for certification of CRMs.

Validation

Certified Reference Materials

The preparation, certification, and distribution of CRMs continue to play a prominent role in calibration and validation of the analytical procedures. Although the number of CRMs for environmental analysis is enormous, the amount of valid data for speciation, biological, geological and nutrition analysis is inadequate. There is also a lack of homogeneous CRMs for geoanalysis using LA. The critical lack of certified isotope ratio standards is a limiting factor in geoisotope studies.

Conclusion

The purpose of the current content is to report on the status of ICP-MS analytical capabilities. ICP-MS in all its variants plays a very important role in trace element geochemistry, environmental, and clinical studies. ICP-MS in its versatility has increased the scope of investigations and together with new and improved sample preparation methodologies has changed the directions of interest and filled knowledge gaps in elemental and isotopic characterization. Enhanced sensitivities and resolution of ICP-SFMS allow direct determination of low-abundance elements, where previous preconcentration was required. The most dramatic recent development is the application of ICP-MC-MS that has resulted in a renaissance in isotope geochemistry and environmental fingerprinting, enabling use of new and different isotopes unattainable using conventional TIMS techniques.

β	angle
γ	angle
ϵ_0	permittivity of vacuum
μ	transition moment
ν	frequency

Induced circular dichroism (ICD) is the CD observed in an optically inactive (achiral) chromophore due to its interaction with an optically active (chiral) moiety. Early applications exploited ICD just as evidence for such an interaction. For example, the ICD in the absorption band of an achiral drug may be used to prove its binding to a (chiral) protein or nucleic acid. More recent use of ICD includes the structural information that theoretical analysis of the inducing mechanism can provide. ICD has been an important complement to linear dichroism (LD) for the assessment of binding geometries in drug–nucleic acid systems.

The CD induced in an achiral chromophore upon interaction with a chiral substrate can be ascribed to one or several mechanisms, each corresponding to a more or less idealized situation: the chromophore molecule may be perturbed, by mainly steric interactions, to adopt a chiral (equilibrium) conformation or it may gain optical activity through electric and/or magnetic interactions with surrounding chromophores.

Different Types of ICD

Strictly, ICD encompasses all kinds of circular dichroism effects except for those of inherently chiral chromophores. This is so because most systems (molecules) may be more or less arbitrarily divided into one achiral chromophore in which the ICD is observed and a remaining component that includes the chirality. Thus, the CD exhibited by a chiral molecule may be considered

ICD if the chromophoric entity itself is achiral. With this broader definition of ICD, molecules such as carbonyl compounds (in which the carbonyl chromophore is achiral) display an intramolecular ICD in the first allowed $n \rightarrow \pi^*$ transition around 300 nm due to perturbation from a surrounding chiral (e.g. steroid) skeleton. Distinction between this type of molecule and one which is an inherently chiral chromophore could be difficult to make as the boundaries of the chromophore are often diffuse. For example, when a diene is in immediate proximity of a carbonyl, a composite chromophore is obtained, which, if skewed, is inherently chiral. Therefore, it is practical to restrict the definition of ICD to cases in which the achiral part is distinctly separable from the chiral part, generally by being a separate molecular species.

ICD could arise in an achiral chromophore mainly through two mechanisms: (1) ICD of an electric dipole-allowed (eda) transition due to coupling with other eda transitions of the surrounding (chirally arranged) chromophore(s) or (2) ICD of a magnetic dipole-allowed (mda) transition due to mixing with eda transitions in the same chromophore under the perturbation of the electronic states of the chiral surrounding. The latter mechanism generally gives more easily detectable ICD as a combined effect of typically strong CD and weak absorption of mda transitions (CD/absorbance sets the limit for the signal-to-noise ratio of CD detection). In addition to carbonyl groups in organic compounds, d–d transitions of transition metals provide examples where strong ICD from interaction with chiral surroundings are frequently observed. For example, the first d–d transition of $[\text{Co}(\text{NH}_3)_6]^{3+}$ displays ICDs of varying sign and magnitude due to hydrogen-bonded outer-sphere coordination with tartrate, amino acids and other chiral oxoanions. These ICD effects have been exploited to assess binding constants of the outer-sphere complexes formed; the strength of the ICD and of the binding constants suggesting that they are due to relatively well-ordered structures. However, attempts towards more detailed structural assignments have been unsuccessful owing to the complicated nature of this mechanism of induced CD. For this reason, the focus here will be on the first (electric dipole) ICD mechanism, which, despite its weaker ICD signals and consequently more demanding experiments, can be more simply related to structural models.

Interactions between Electric Dipole-Allowed Transitions

This mechanism of ICD is related to the strong exciton CD that is observed for a chirally arranged set of identical intense absorbers such as in a chiral homodimer (or polymer) species. A characteristic feature is the strong bisignate CD doublet observed at the frequency of the transition. The dominant CD bands centred around 200 nm in proteins and at 260 nm in nucleic acids are both of exciton-type $\pi \rightarrow \pi^*$ transitions. Exciton CD will not be considered an ICD as the transition is not localized on a single achiral chromophore but is spread over the whole dimer (polymer) system and thus constitutes an inherently chiral chromophore. Instead, the ICD arises from the interaction between two different (nondegenerate) chromophores. It is generally of a much weaker magnitude than the exciton CD, but becomes gradually more intense as the energy between the two transitions decreases. This is seen from the energy difference in the denominator of the expression (eqn [1]) for the ICD rotational strength $R(A)$ for an eda transition, with transition moment $\mu(A)$ occurring at frequency $\nu(A)$ on chromophore A, due to interaction with another transition $\mu(B)$ at frequency $\nu(B)$ on chromophore B of the chiral environment. A requirement for non-vanishing $R(A)$ is that the transition moments $\mu(A)$ and $\mu(B)$ are chirally arranged relative to each other, that is, they must not be coplanar (**Figure 1**).

$$R(A) = \frac{-2\pi\nu_A\nu_B}{bc(\nu_B^2 - \nu_A^2)} V_{BA} O_{BA} \quad [1]$$

where V_{BA} is the corresponding dipole–dipole interaction energy:

$$V_{BA} = \frac{1}{4\pi\epsilon_0} \frac{1}{|R_{BA}|^3} \left[(\mu_A \cdot \mu_B) - \frac{3}{|R_{BA}|^2} \times (\mu_A \cdot R_{BA})(\mu_B \cdot R_{BA}) \right] \quad [2]$$

where μ_A and μ_B are the two (unperturbed) electronic transition moments, ϵ_0 is the permittivity of vacuum, and R_{BA} is the vector from the centre of A to the centre of B. O_{BA} in eqn [1] is an ‘optical factor’ which depends on the geometrical arrangements of the two electronic transition

Figure 1 Geometry and coordinates of the A–B system. Transition moments μ_A and μ_B of chromophores A and B and the separation vector R_{BA} .

moments relative to each other:

$$O_{BA} = R_{BA} \cdot (\mu_A \times \mu_B) \quad [3]$$

A decreased difference between $\nu(A)$ and $\nu(B)$ in the denominator of eqn [1] would make $R(A)$ increase; consequently, ICD of bands close to the inducing band would be strong. The ICD further depends on the geometry of the A–B pair, both through V_{BA} (eqn [2]) and O_{BA} (eqn [3]), which could be described by four coordinates: the length of the separation vector R_{BA} and three angles α , β , and γ defining how $\mu(A)$ and $\mu(B)$ are oriented relative to R_{BA} . As seen from eqns [2] and [3], the interaction factor V_{BA} and the optical factor O_{BA} of eqn [1] are both dependent on all four coordinates. The ICD drops off as R_{AB}^2 as a combined effect of the R_{BA} dependences in eqns [2] and [3]. Furthermore, the ICD is proportional to the dipole strengths μ_A^2 and μ_B^2 , i.e. to absorption of both A and B chromophores:

$$R(A) = -\frac{2\pi\nu_A\nu_B(\mu_A\mu_B)^2}{bc(\nu_B^2 - \nu_A^2)R_{BA}^2} (\sin\alpha \sin\beta \cos\gamma + 2\cos\alpha \cos\beta) \sin\alpha \sin\beta \sin\gamma \quad [4]$$

Generally, the achiral chromophore A interacts with several chromophores (B_i) of the chiral substrate. If $\nu_A \ll \nu_B$, the ICD may be regarded as a sum of pairwise contributions, each corresponding to one term in eqn [1] with a given set of B_i , V_{BiA} and O_{BiA} . In many molecular systems, such as DNA and cyclodextrins, the symmetric distribution of B chromophores makes it possible to deduce simple expressions for the net ICD.

The following examples will focus on studies of DNA-induced circular dichroism; however the principles are general, based on the application of eqns [1]–[4].

Detection and Quantitation of DNA–Drug Complex

Many DNA-binding molecules (usually referred to as ligands or drugs although they may have little or no therapeutic value) are themselves achiral. However, upon binding to DNA, they acquire an ICD that is characteristic of their interaction. When considering CD applications of proteins and DNA, the ligand ICD can be used at a number of levels. The simplest use is to note that it exists, and therefore that the molecule *does* bind to the chiral substrate; however, more information can usually be extracted.

Empirical Use of ICD for Binding Site Analysis

It is often useful to measure a series of spectra where some variable such as temperature, ionic strength, or mixing ratio (drug: DNA ratio) is changed. If the CD intensity changes but the shape of the spectrum remains

constant during such an experiment, this indicates that the ligand binding mode is unchanged although the amount of bound ligand may have changed. If, however, there is a change in the shape of the spectrum as an experimental parameter is changed, then a change in the DNA–drug interaction as a function of that parameter is implied. The change is frequently due to occupancy of more than one binding site as the drug load of the DNA increases. Alternatively, it may also be due to changes in DNA conformation or to drug–drug interactions. In other words, if the experiment is conducted with a constant ligand concentration and varying DNA concentration, then unless the ligand binding mode is changing, there should be no change in the observed ligand ICD. A particularly dramatic change, due to exciton CD, is observed if, as the DNA concentration is decreased, the ligands begin to stack or self-associate with each other.

Extended Treatment for Structural Analysis

The important case of coupled oscillator (exciton) CD of interacting, identical chromophores (i.e. degenerate transitions) has already been mentioned. Exciton CD was observed for dye molecules upon association to biopolymers, attributed to interactions between adjacently bound dimolecules with chiral orientation relative to each other. The less exploited case of coupling of the electric dipole transition of the ligand molecule A due to interaction with one or several *nondegenerate* transitions of the chiral molecular system B has been considered in terms of eqns [1]–[4]. Because of the nondegeneracy, this CD is generally very small and should be measured at low drug:biopolymer ratios to avoid dominance by the much more intense exciton CD from drug–drug interactions. DNA-induced monomer CD is exhibited by, for example, intercalating dyes such as methylene blue, acridine orange and proflavin. The DNA-induced CD of several of these intercalators depends sensitively both on salt conditions and on base sequence. These effects have been interpreted in terms of varying binding geometries in the intercalation pocket or to varying inducing transitions of the nucleobases. For eda drug transitions which are energetically isolated from the inducing transitions of the DNA bases, a simple relation has been derived between the DNA-induced monomer CD (rotational strength R) and the ‘azimuthal’ angle γ , defining the orientation of the intercalator transition in the plane of the intercalation pocket (angle to dyad axis):

$$|R| = f|\mu|^2(1 - 2\cos^2\gamma) \quad [5]$$

where f is a function comprising contributions of the various transitions of the surrounding nucleobases. The

Figure 2 (a) ICD of a DNA intercalator calculated as a function of the transition moment in the plane of the intercalation pocket and centred on the helix axis. γ is the angle between the transition moment and the DNA dyad axis. Reproduced with permission from Lyng, Hard, and Nordén (1987) *Biopolymer* 26: 1327. (b) definition of geometrical parameters of a DNA–ligand system: with $r=0$, $\alpha=90^\circ$ and $\beta=0^\circ$, then γ corresponds to the orientation of an intercalator transition moment (see top figure). Typical minor groove binding geometry parameters are $r=7 \text{ \AA}$, $\alpha=45^\circ$, $\beta=0^\circ$ and $\gamma=0$.

DNA-induced CD of an intercalator has also been calculated using the more rigorous ‘matrix method’. The orientation dependence obtained in this manner (Figure 2) was found to be in good agreement with the $(1 - 2\cos^2\gamma)$ dependence predicted by eqn [2]. The CD amplitudes were also in reasonable agreement with measured ICD spectra of various intercalators which can be seen in Table 1.

The situation is more complicated for a non-intercalator than for an intercalator in that there will be more degrees of geometrical freedom (Figure 2) and, as a result of the external position, interactions with a larger number of DNA bases must be considered.

Groove-Bound and Intercalator Ligand–DNA Complex Geometries

The relative geometries of DNA and the transition moment of an externally bound chromophore are defined by the parameters r , α , β , and γ , in Figure 2b. r and γ define the *position* of the external chromophore’s transition moment relative to the DNA helical axis and α and β

Table 1 Calculated and observed ICD rotational strengths for DNA intercalators and externally bound drugs

Drug system ^a	Energy of transition (10° cm ⁻¹)	Transition moment angles (Figure 2)(°)			Rotational strength (DBM units)	
		α	β	γ	Expt.	Calc./predicted
Intercalators						
DAPI-[Poly(dC–dG)] ₂	30	80	0	0	+0.01	+0.01
Acridine orange–DNA	20	90	0	90	–	–
Pseudoisocyanine–DNA	18	90	0	90	–	–
APF–[poly(dC–dG)] ₂	28	80	0	0	+	+
Minor groove binders						
DAPI–[poly(dA–dT)] ₂	30	45	0	90	+1.8	+0.5
Netropsin–DNA	32	45	0	90	+1.3	+0.4
Hoechst 33258–DNA	26	45	0	90	+2.8	+0.4
APF–[poly(dA–dT)] ₂	28	45	0	90	+	+
Major groove binders						
Methyl green–DNA	23	90	180	0	–0.6	–0.1
	15	45	180	270	+0.8	+0.2

^aDAPI = 4,6-diamidino-2-phenylindole and APF = 2,5-bis(4-aminophenyl)furan.

Figure 3 Example of ICD calculated for a minor groove binder (at the 5'G-3'C step) as a function of angles α and β (see Figure 2). Reproduced with permission of Wiley from Lyng, Hard, and Nordén (1991) *Biopolymers* 31: 1709.

describe the *orientation* of the transition moment; α is the angle between the z -axis (DNA helical axis) and the transition moment and β is the angle between the projection of the transition moment onto the xy plane and the vector r the distance from the helix axis to the position of the transition moment.

In Figure 3, an example is shown of the ICD calculated for a nonintercalator ($r = 7 \text{ \AA}$) sitting outside a GC step in the minor groove, as a function of the α and β angles. $\alpha = 45^\circ$ and $\beta = 90^\circ$ correspond to a minor groove binding geometry (indicated by an $\times$), with a transition moment pointing along the groove. This geometry should give a

strong positive ICD. However, $\alpha = 90^\circ$ and $\beta = 0^\circ$, which correspond to a transition moment along the duplex dyad axis of an intercalator which has been withdrawn from the centre, should produce a negative ICD. A strong positive ICD appears to be a common feature for minor groove binders with transition moments parallel with the groove. However, depending on the DNA sequence, both the sign and amplitude are predicted to vary for other non-intercalated and semi-intercalated geometries.

As can be seen in Table 1, DAPI and APF, which are both known to bind preferentially, in the minor groove at AT-rich regions of duplex DNA, can also bind by intercalation in pure GC tracts (this difference is most clearly seen in the flow linear dichroism spectrum, which probes the α angle). Thus, Figure 4 shows three types of DNA ICD. Spectrum (a) shows the APF [2,5 bis(4-aminophenyl)furan] ligand bound in the minor groove of [poly(dAdT)]₂. Spectrum (f), obtained at a higher drug:DNA binding ratio, also contains a contribution from exciton CD due to drug-drug interactions between adjacent sites in the minor groove. Spectrum (g), which refers to APF in [poly(dGdC)]₂, is the weak positive CD corresponding to the intercalated drug with the transition moment preferentially directed along the short (dyad) axis of the intercalation pocket.

Conformational ICD in DNA Systems
